versions 2.6 through 3.4 were maintained by
     dr. a. p. mccann
     department of computer studies
     university of leeds
     leeds ls2 9jt
     england.
from 1979 through early 1983 a number of fixes and
enhancements were made by steve duff and robert goldberg.
to assist implementors a revision history based on
version 2.7 is being maintained.
```

spitbol–revision history

r e v i s i o n h i s t o r y
---
version 3.6a to 3.7 (november 1, 1991, mark b. emmer)
---
bugs fixed
---
b3.701 add btkwv and refined test at cdgvl+9 to prevent variable names alphabet, lcase, ucase from being pre-evaluated because of their associated constant keywords. the code

```
alphabet = "abc"; output = size(alphabet)
```

returned zero because of pre-evaluation.

b3.702 delay binding to function block of fourth argument to trace function. this permits the trace function to be invoked before the 4th argument function is defined. accomplished by storing a vrblk pointer in trfnc, and fetching its vrfnc entry later, in trxeq.

b3.703 references to keywords with constant pattern values (&arb, &bal, etc.) did not work. a wtb instruction had been omitted at acs14+2.

b3.704 if a program employed the code function to redefine a label that was the entry location of a user-defined function, the function would continue to jump to its old function body. pfcod in pfblk was pointing directly to the target code block, instead of doing so indirectly through the vrblk for the entry label.

b3.705 the test that required a label to be defined before it could be used as the entry of a user-defined function has been removed. functions may be defined even if the label is yet undefined.

b3.706 after a compilation error in the code function, the eval function produces spurrious errors. the code offset cwcof was not being reset to the beginning of code block. add line at err04+1 to accomplish this reset.

b3.707 inconsistant tests with mxlen corrected. several places were testing with bge instead of bgt, resulting in such anomalies as the statement

```
&maxlngth = &maxlngth
```

failing. since mxlen is guaranteed to be strictly less than dnamb, it is permissible to create objects of size mxlen. bge changed to bgt at locations

```
s$arr+14, sar07+8, alobf+3, asg14+8, gtar6+10.
```

b3.708 exit(command string) was not loading ptr to fcb chain into wb. corrected at sext1.

b3.709 change patst to return non-string error for null argument. previously, break(), any(), etc., were succeeding, contrary to the language definition.

b3.710 convert function with null second argument

```
        crashed system by calling flstg with wa=0.  added
        test at s$cnv, moved error 74 to separate erb at
        scv29.
b3.711  leq(,) crashed system.  lcomp did not obey
        minimal assumption that cmc opcode will always
        be called with wa .gt. 0.  added test at lcmp1.
b3.712  modified line at sdf07+4 to use register wa
        instead of wb.  this corrects problem of define
        function with local variable list that begins
        with comma-  define("f(x),l1,l2")
b3.713  erroneous plc on uninitialised r$cim in listr.
b3.714  erroneous call to flstg possible with null string
        at sdat1.
b3.715  when copy function used with table argument, fix
        problem at cop07.  when copying first teblk on a
        chain, the pseudo-previous block pointer in xr
        is pushed on the stack prior to calling alloc.
        this is not a valid block pointer, as it points
        within the tbblk.  if the subsequent alloc
        invokes gbcol, the heap becomes scrambled.
        recoded to save pointer to start of block, plus
        offset in wb.
b3.716  at iop01, if gtvar triggered garbage collection
        via alost, trap block in wc was not collected.
        save wc on stack to make it collectable across
        gtvar call.
b3.717  at asg10, allow case of variable with more than
        one trblk, as happens with the following stmt -
        output(.output, .output, filename).
b3.718  at senf1, trblk chain search was reloading chain
        head, causing infinite loop if the desired trblk
        was not the first on chain.  system crashed with
        trace(.v1) output(.v2,.v1,file).
b3.719  prototype strings (define, load, data, etc.) were
        allowing blank characters, producing bogus
        variable names.
b3.720  the fact that iofcb destroyed register wc was not
        documented.  b$efc conversion of file argument
        never worked because wc and xt were destroyed by
        call to iofcb.
b3.721  ioput left a trblk attached to filearg1 if sysio
        failed.  subsequent use of this filearg1 variable
        in another i/o call would crash system.
b3.722  add chk at evlp1 to catch recursive pattern error.
b3.723  allow -line to work properly within code function
        by setting cmpln directly in cnc44.  if file name
        absent, decrement scnpt to rescan terminator.
b3.724  when mxlen exceeds start of dynamic memory, round
        it up to multiple of word size prior to storing
        in dnamb at ini06.
b3.725  provide right padding of zero characters to any
        string returned by an external function.
b3.726  reset flptr at bpf17 for undefined function
```

```
        when evalx is evaluating an expression.
b3.727  modify code after read5 for outer nesting of
        an execute-time compile of -include statement.
        create a substring of remainder of original
        code function argument string and return as
        result of readr function
b3.728  the definition of the aov opcode is corrected.
        formerly the definition specified that the branch
        was to be taken if the result of the addition
        exceeded cfp$m, implying a test for overflow
        from signed addition.
        however, address arithmetic must be unsigned to
        allow for systems where the high order address
        bit is set.  therefore, the test must be for
        carry out of the high order bit, if the result
        would exceed cfp$l.
b3.729  a label trace on the entry label for a function
        was undetected, resulting in a transfer to
        b$trt and subsequent crash.  see bpf08 for fix.
b3.730  pop first argument to substr if it is a buffer.
b3.731  pattern replacement with buffer subject returned
        null string instead of new subject value.
        changed to behave as if subject was a string.
b3.732  if convert function was called with a buffer
        first argument and "buffer" second argument,
        it would convert the buffer to a string, and
        then back to a buffer.  this has be corrected
        to simply return the first argument as the
        function result.
b3.733  detect external function returning a null string
        unconverted result at bef12, and jump to exnul.
b3.734  fix problem at ins04 when inserting zero length
        string into buffer.  defend against invoking
        mvc with a zero value in wa, which will cause
        some implementations to wrap the counter.
b3.735  add overflow test for cos and sin to detect
        out-of-range argument.
b3.736  fixed problem introduced with b3.727 not
        restoring r$cim, scnpt and scnil after creating
        substring.
b3.737  fixed tfind to place default value in newly
        allocated teblk.
b3.738  added bl$p0 to p$nth entry point.  the expression
        datatype(convert("","pattern")) would crash when
        the dtype function uses the non-existant type
        word preceding p$nth.
b3.739  bug at gtn35 in the case of overflow during cvm.
        wb can be destroyed by cvm on some platforms.
b3.740  protect scontinue from usage in other than error
        320 case.
b3.741  protect continue from usage following error
        evaluating complex failure goto.
changes
```

```
-------
c3.701  add .culk conditional to include &lcase, &ucase.
c3.702  add -line nn "filename" control card.
c3.703  move .cnld conditional up in routine dffnc to
        omit all tests for b$efc.
c3.704  add conditional .cicc to ignore unrecognized
        control cards.
c3.705  add conditional .cnsc to omit string to numeric
        conversion in sort.  the presence of this
        conversion mode produces a sort result that is
        dependent upon the order of input data.
        for example, given input data "2", 5, "10",
        string comparison yields "10" lt "2", but string
        to integer conversion yields "2" lt 5 lt "10".
c3.706  add seventh return from syshs that allows callee
        to return a string pointer and length.  this is
        done to eliminate the need for the caller to have
        an scblk big enough to accommodate long strings.
c3.707  add eighth return from syshs to force copy of
        block pointed to by xr.
c3.708  made -copy a synonym for -include.
c3.709  add conditional .cbyt for statistics displayed
        in bytes rather than words.
c3.710  dump null valued variables when dump = 3.  core
        dump produced for dump = 4.
c3.711  restrict minimum value to which keyword maxlngth
        can be set to 1,024 via new variable mnlen.
c3.712  add conditional symbol .cmth for extended math
        functions- atan, chop, cos, exp, ln, sin, sqrt,
        tan.  x**y and remdr(x,y) are extended to include
        reals.
c3.713  add bit to syspp to set -print upon entry
c3.714  add conditional .csfn to track source file name
        associated with each code block.
c3.715  add conditional .cinc for -include control card
        feature.  the format of the card is
           -include "filename"
        include control cards may be used during both the
        initial compile and execute-time compile.  the
        filename is saved in a table, and redundant
        includes of that file are ignored.
c3.716  add conditional .csln to include source line
        number in code blocks.  release current ccblk
        after initial compile.
c3.717  changed rilen to 258 (from 120) to provide
        uniform input line length when reading from
        terminal or input.
c3.718  add additional exit to iofcb to distinguish
        argument not convertable to string and argument
        file not open.
c3.719  add fourth and fifth arguments to host function.
c3.720  add &compare keyword to control string
        comparisons.
```

```
c3.721  setup pfdmp at iniy0 in case osint forced
        &profile non-zero.
c3.722  add conditional symbol .caex to include up arrow
        as synonym for exponentiation.
c3.723  add conditional .ccmc and external function syscm
        to provide string comparison using collation
        sequence other than strict ordering of character
        codes (international compares).
c3.724  add conditional .cpol and external function syspl
        to provide interactive control of spitbol
        execution.
c3.725  add conditional symbol .cera and external
        function sysea to provide advice of compilation
        and runtime errors to osint.
c3.726  add cmpln, rdcln, rdnln to track source line
        number.
c3.727  converted error messages to upper/lower case.
c3.728  add conditional .cgbc to external routine sysgc.
        called at the start and end of garbage collection
        to perform any needed notification to operating
        system or user.
c3.729  modified last line of s$set from exnul to exint
        so seek can return final file position after
        seek.
c3.730  place mov xr,(xs) at s$rmd+4 to allow real second
        arg to remdr.
c3.731  remove redundant bge xr,=cfp$u,scn07 at scn06+4
c3.732  change definition of cmc and trc such that only
        xl must be cleared after operation.  note, this
        change was subsequently voided.  cmc and trc must
        clear both xl and xr, because utility routines
        may preserve xl or xr on the stack, and the stack
        is collectable by gbcol.
c3.733  remove most branches to exits and exixr.
        instead, jump directly to next code word.
c3.734  add error 260 for array too large in gtarr.
c3.735  add conditional .cs32 to initialize stlim to
        2147483647.
c3.736  add second argument to exit function, allowing
        user to specify file name of load module being
        written.  if omitted, osint will provide a
        default name.
c3.737  add conditional .cspr to include spare locations
        in working area.  these may be used in later bug
        fixes without changing the size of the working
        storage and obsoleting modules created by exit().
        subsuently removed in c3.767.
c3.738  add r$cts to remember last string used to build
        bit column in patst.
c3.739  change flstg to type e procedure instead of r.
c3.740  standardize on big-endian systems.  at the
        implementors choice, the zgb opcode can also
        perform a byte swap if necessary to achieve big-
```

endian byte ordering. this is done so that systems with similar word lengths will produce the same hash code for strings, and hence the same ordering for table entries. the hashs procedure has an additional zgb added to reorder the length word.

c3.741 add conditional .csou to cause assignments to output and terminal variables to be processed through calls to sysou rather than through listing buffer. done to eliminate short record lengths enforced by buffer size. a code of 0 or 1 is passed to sysou instead of an fcblk.

c3.742 increased iniln, inils, rilen to 1024.

c3.743 add bit to syspp to set noerrors mode.

c3.744 add .ccmk conditional to include keyword compare even if syscm is not being included. done to provide identical data regions in systems that implement syscm and those which do not, so that save files can be exchanged in the next release.

c3.745 add wc return parameter to sysil to allow interface to inform spitbol if file about to be read is a binary file. if so, no blank trimming occurs.

c3.746 fold load function argument types to upper case.

c3.747 add .cexp conditional to have sysex pop its arguments.

c3.748 in stopr, do not attempt to display file name and line number if stopping because of stack overflow during garbage collection. pointers to file name table and code block are wrong.

c3.749 add bit to syspp to set case folding mode.

c3.750 add additional return from sysld if insufficient memory to load/call external function.

c3.751 add additional returns from sysex if insufficient memory or bad argument type.

c3.752 ignore leading and trailing blanks in arguments within prototype strings to clear, data, define and load.

c3.753 test for fatal error at err04 and abort if so. force termination on stack overflow by setting errft to 4 in stack overflow section.

c3.754 recode copy loop at srt14 to exchange usage of registers xl and xr. this permits use of the mvw order instead of the explicit loop coding previously employed.

c3.755 add .ceng conditional to include routines needed by text processing engine. add routines enevs and engts for use by engine or debugger. copy xr to xl around call to syspl to allow syspl to trigger garbage collection.

c3.756 add &file, &lastfile, &line, &lastline keywords. for now, line and lastline are maintained in the same manner as stno and lastno, which adds over-

head to the statement initialization code. a possible change is to create a stmln procedure that maps statement numbers to line numbers. one simple strategy would be to sweep code blocks in memory looking for the statement number and extracting the line number from that code block. such a procedure would also allow line numbers (and file names) to be added to statement profile reports.

c3.757 change sort to fail instead of producing error message if argument table is null. change sorta to return failure. add another return to gtarr to distinguish null table from bad argument.

c3.758 create procedure prtmm to display memory usage statistics, and call it when producing end-of-run stats.

c3.759 add label scontinue to allow setexit to resume execution exactly where it was interrupted.

c3.760 add snobol4 backspace function and conditional .cbsp.

c3.761 add additional arguments to sysgc to assist virtual memory managers.

c3.762 the method of converting a table to an array has been revised. previously, table elements were copied to the result array in the order they were encountered along the various hash chains. this appeared to the user as a random ordering. however, spitbol/370 as well as sil snobol4 ordered array elements according to their time of entry into the table. user programs that relied upon this behavior malfunctioned when ported to macro spitbol.

to remedy this, the conversion is performed in three steps:

1. convert table to an array placing the address of each teblk in the array instead of the key and value.
2. sort the array of addresses. this orders elements by time of creation (ascending address).
3. scan the array, replacing addresses with the key and value from the referenced teblk.

the affected portions of the program are at s$cnv and in gtarr, which now accepts an additional argument specifying whether to place key/values in the array or teblk addresses.

c3.763 if case-folding is active, fold the function name provided to the load() function before passing it to sysld.

c3.764 add sediment algorithm to garbage collector, conditioned on .csed.

c3.765 add optimization to discard null statements and statements which just have a constant subject (see code at cmp12).

```
c3.766  rearranged order of initial objects in static
        memory so that hash table is the last of the four
        object created by initialization code.  this is
        done so that the print buffer, gts work area, and
        &alphabet keywords do not need to be saved in
        any save file created by osint.  added routine to
        initialize these structures.
c3.767  removed .cspr conditional and spare locations.
c3.768  added .crel conditional and extensive routines
        (reloc et. al.) to perform relocation of data
        in working section, static region, and dynamic
        region after reload of a saved memory image.
        routines relaj, relcr, and reloc are invoked
        by osint after reloading a save file.
        it is now possible to reload such an image even
        if the spitbol compiler and its data structures
        are reloaded to other addresses.  the working
        section has been extensively rearranged to
        accommodate the reloc procedure.
c3.769  zero r$ccb (interim ccblk ptr) in collect,
        convert, eval, and exit functions to release
        unneeded ccblk memory.
c3.770  add exit(4) and exit(-4) to allow execution to
        continue after writing save file or load module.
        revised sysxi interface to detect continuation
        after performance of exit(4) or exit(-4) action.
c3.771  change filnm to preserve registers.
c3.772  addition of .cncr and syscr (real to string
        system routine option).
c3.773  modified replace function to optimize usage
        when second argument is &alphabet.  in this case,
        the third argument can be used as the translate
        table directly.
c3.774  modified conditionals for buffers and reals so
        that their respective block codes are always
        present, even if these data types are conditioned
        out.  this provides consistent block code
        numbering for external functions.
c3.775  modified alobf to test string length against
        kvmxl instead of mxlen.  also, alobf was testing
        total size of bfblk, instead of just string len.
c3.776  move utility routines source up to lie between
        predefined snobol functions (s$xxx) routines and
        utility procedures.  this was done to assist
        translation on platforms such as apple macintosh
        that use 15-bit offsets to store error exits (ppm
        branches).  offsets to labels like exfal were
        just too far away.  similarly, functions tfind,
        tmake, and vmake are located out of alphabetic
        order to satisfy the macintosh's limited range
        for subroutine calls.  move built-in labels
        beyond the block and pattern routines to get it
        within 32k of the error routines.
```

c3.777 at scn46, allow colon, right paren and right bracket to terminate = operator with default null operand.

c3.778 added .ctet conditional for table entry trace.

c3.779 introduce cfp$l, the largest unsigned value that may be stored in a one-word integer. this is done to accommodate machines where memory addresses have the high-order address bit set.

c3.780 perform replace in place if first arg is buffer.

c3.781 perform reverse in place if first arg is buffer.

c3.782 change sysou to accept buffer as well as string to be output. change code at asg11 to prevent conversion of buffer to string.

c3.783 optimize pos and rpos when it is the first node of a pattern and has either an integer or simple expression variable argument. if unanchored mode and the cursor is zero, it is advanced directly to the desired cursor position.

c3.784 perform trim function in place if arg is buffer.

c3.785 add gtstb procedure to get a string or buffer argument for replace, reverse, size, trim, etc.

c3.786 change leq, lgt, etc. to perform comparisons without converting buffer arguments to strings. this is done by changing lcomp to accept buffer argument(s). this also affects sort function, which will compare two buffers as strings.

c3.787 change gtnum to use characters in buffer without conversion to a string. this implies that acomp will perform arithmetic comparisons of buffers without converting to strings first.

c3.788 perform comparisons of strings and buffers in sortc.

c3.789 change insbf to allow insertion of a buffer into a buffer without first converting it to a string. note that this only works when the two buffers are not the same.

c3.790 documentation change: note that all of the block move opcodes should have wa .gt. 0. not all implementations avoid moving objects when wa is zero.

c3.791 change ident to provide buffer/buffer and buffer/string comparisons, to accommodate users who perform ident(buf) to check for null string in buffer.

c3.792 added fullscan keyword initialized to one. user may set to any non-zero value, will receive an error message if attempts to set to zero, since quickscan mode is not supported.

c3.793 rewrote statement startup code at stmgo to only perform checking of profiling, stcount tracing, and statement counting if necessary.

c3.794 add additional exit to sysfc and ioput to signal that i/o channel (fcblk) is already in use.

```
        added error message numbers 289 and 290.
c3.795  added optional integer argument to date function
        to specify format of date string returned by
        sysdt.
version 3.6 to 3.6a (oct 83)
----------------------------
changes
-------
c3.617  add .cnlf. if defined, then arguments to external
        functions may be declared to have type file.
        such arguments must have been used as second
        arg to input() or output() and a pointer to the
        fcb is passed to the external function.
version 3.5 to 3.6 (jun 83)
---------------------------
codes used to identify authors are (sgd) for duff,
(reg) for  goldberg, and (lds) for shields.
bugs fixed
----------
b3.601  (sgd) to fix multiple trap block problem in asign
b3.602  (sgd) patch in gtarr to fix null convert.
b3.603  (sgd) inserted missing wtb after sysmm calls.
b3.604  (sgd) use string length in hashs.
b3.605  (sgd) fixed serious parser problem
        relating to (x y) on line being viewed as pattern
        match.  fixed by addition of new cmtyp value
        c$cnp (concatenation - not pattern match).
b3.606  (sgd) fixed exit(n) respecification code
        to properly observe header semantics on return.
b3.607  (sgd) bypass prtpg call at initialization
        following compilation if no output generated.
        this prevents output files consisting of the
        headers and a few blank lines when there is no
        source listing and no compilation stats.
        also fix timsx initialization in same code.
b3.608  (sgd) b$efc code did not check for
        unconverted result returning null string.
b3.609  (sgd) load pfvbl field in retrn for
        return tracing. this was causing bug on return
        traces that tried to access the variable name.
b3.610  (sgd) fixed problem relating to compilation of
        goto fields containing small integers
        (in const sec).
b3.611  (reg) prevent clear() from clobbering protected
        variables at label sclr5.
b3.612  (reg) fixed gtexp from accepting trailing
        semicolon or colon. this is not a legal way
        to end an expression.
b3.613  (reg) fixed difficulties with listings during
        execution when no listing generated during
        compilation. -list to code() caused bomb.
        fix is to reset r$ttl and r$stl to nulls not 0
        after compilation.
```

```
        (listr and listt expect nulls)
        when listing and statistics routed to different
        file than execution output, error message is sent
        to execution output (and gets separated from
        ... in statement ... msg). labo1 calls sysax and
        stopr does not call sysax if entered from labo1.
b3.614  (lds) fix misuse of wc just after asg10.
b3.615  (lds) add comment pointing out suspicious code
        after tfn02
b3.616  (lds) fix inconsistent declaration of sorth.
b3.617  (lds) insert missing conditional tests on cnbf.
b3.618  (lds) fix some violations of minimal language
        that had slipped past some translators.
b3.619  (lds) correct error introduced in fixing b3.614.
```

```
changes
-------
c3.601  (sgd) addition of .cnci and sysci (int to string
        system routine option)
c3.602  (reg) changed iniln and and inils to 258
c3.603  (sgd) merged in profiler patches, repaired code.
c3.604  (sgd) added buffer type and symbol cnbf
c3.605  (sgd) added char function.  char(n) returns nth
        character of host machine character set.
c3.606  (reg) added cfp$u to ease translation on smaller
        systems - conditional .cucf
c3.607  (reg) added lower case support, conditional .culc
c3.608  (reg) added set i/o function, conditional .cust
c3.609  (reg) conditionalized page eject after call to
        sysbx and added another before call to sysbx,
        so that, if desired by the implementor,
        standard output will reflect assignments made
        by executing program only.
        conditional .cuej controls - if defined then
        eject is before call to sysbx.
c3.610  (lds) introduce .ctmd to support systm that
        reports elapsed time in deciseconds instead of
        milliseconds.
c3.611  (lds)  provide place for .def or .und for each
        conditional  option, so that settings can be
        changed without changing line numbers.
        current settings are for 808x translation.
c3.612  (lds) obey (new) restriction that operand in
        conditional branch instruction cannot have form
        (x)+ in order to simplify translations for which
        postincrement not readily available.
c3.613  (reg,lds) add op
              flc wreg
        that folds character in wreg to upper case.
        this op is used only if .culc is defined.
        this change also involves addition of keyword
        &case which when nonzero (the initial setting)
        causes the case folding just described to be
        done.
c3.614  (lds) add option .cs16 to permit initialization
        of statement limit values to 32767 for 16 bit
        machines.
c3.615  (lds) permit return point and entry point
        addresses to be distinguished by their parity
        instead of by lying within a certain range
        of values.  introduce conditional symbols
        .crpp  return points have odd parity
        .cepp  entry points have odd parity
c3.616  (lds) introduce new minimal opcodes to branch
        according to parity,
          bev  opn,plbl  branch if address even
          bod  opn,plbl  branch if address odd
        an address is even if it is a multiple of cfp$b.
```

```
documentation revisions
-----------------------
d3.601  (lds) bring minimal machine description up to
        date
```

```
version 3.4 to 3.5 (feb 79)
---------------------------
bugs fixed
----------
b3.401  prtst should be declared as an r type procedure.
b3.402  timing error if spitbol fails in dump.
b3.403  error in handling omitted args of operators.
b3.404  too many lines put on first page of listing.
b3.405  leading unary operator in eval erroneously needed
        preceding blank.
b3.406  identifying name in dump of array or table values
        was omitted.
b3.407  eval unable to return a deferred expression.
b3.408  illegal if setexit code branches to return.
b3.409  illegal on detaching input, output, terminal.
changes
-------
c3.401  -sequ and -nose control cards removed.
c3.402  option provided to suppress system identification
        on listing.
c3.403  description of sysbx slightly revised.
c3.404  permissible to modify scblk length before taking
        error returns from sysin, sysrd, sysri.
c3.405  conditional .cnld may be defined to omit load().
c3.406  conditional .cnex may be defined to omit exit().
c3.407  table now accepts a third argument specifying
        default initial lookup value.
c3.408  routines sort, rsort for sorting arrays and table
        introduced. specification is as in sitbol.
        routines may be omitted by defining .cnsr .
c3.409  error in code(), eval() call now causes statement
        failure but errtext keyword is still set.
c3.410  arg to code() may contain embedded control cards
        and comment delimited by a semicolon.
documentation revisions
-----------------------
d3.401  purpose of restriction 2 in minimal section -6-
        (operations on char values), erroneously stated
        to be for cmc, rather than for ceq, cne.
        descriptions of above opcodes revised.
d3.402  description of ent clarified.
d3.403  descriptions of several opcodes revised to remove
        technically invalid literals e.g. =0 , *1.
d3.405  restricted use of letter z in minimal clarified.
d3.406  divide by zero explicitly mentioned in relation
        to overflow setting.
```

```
version 3.3 to 3.4 (oct 78)
---------------------------
bugs fixed
----------
b3.301  illegal for erroneous eval() arg.
b3.302  address arithmetic overflow in alloc and alocs.
b3.303  -eject and -space ignored -nolist option.
b3.304  erroneous argument scan in load().
b3.305  erroneous plc on uninitialised r$cim in nexts.
b3.306  ldi used instead of mti after prv07.
b3.307  misuse of rmi at erra2.
b3.308  misuse of mti in hashs.
b3.309  bug in -sequ card sequence number checking.
b3.310  stack overflow error message not always printed.
b3.311  corrupt prototype print for traced arrays.
b3.312  pattern first arg in dupl caused error.
b3.313  omitted csc in s$rpd, erroneous csc in convert.
b3.314  misplaced btw in exbld.
b3.315  incorrect code in hashs.
b3.316  failure of load to scan integer arg.
b3.317  table access with negative integer arg. failed.
b3.318  error in returning result of loaded function.
b3.319  =e$srs used after ini01 instead of *e$srs.
b3.320  err used instead of erb after systu
b3.321  label could start with disallowed character.
b3.322  continue after setexit had bad heuristic.
```

```
changes
-------
c3.301  sysax and .csax introduced - see sysax
        in procedures section.
c3.302  variable mxlen introduced. contains the maximum
        size of a spitbol object and is not changeable
        after initialisation. may be defaulted or set
        explicitly by sysmx.
c3.303  syshs returns revised - see syshs.
c3.304  new minimal opcode aov to fix b3.302.
c3.305  inhibit stlimit check if stlimit made negative.
c3.306  cfp$m is required to be of form 2**n - 1.
c3.307  dupl made to conform to sil snobol4 standard.
c3.308  lch and sch actions more closely defined.
c3.309  batch initialisation code omitted if conditional
        assembly symbol .cnbt (no batch) defined.
c3.310  (wa) contains argument count in sysex call.
c3.311  sysfc  may request allocation of static fcblk.
c3.312  if ia,wc overlap, restriction put on dumping/
        restoring these registers.
c3.313  new listing option intermediate between compact
        and extended provided (see syspp).
c3.314  revision of sysxi interface to permit options for
        load module standard o/p file (see sysxi,syspp).
c3.315  last arg of substr may be omitted - treated
        as remainder of string.
```

```
version 3.2 to 3.3 (jan 78)
---------------------------
bugs fixed
----------
b3.201  array reference and external function load
        routines illegally accessed information
        beyond the stack front.
        similar fault in unanchored pattern matching.
b3.202  dump(1) produced dump(2) type output.
b3.203  wtb conversion omitted in code following
        ini01, ini02, exbld.
b3.204  incorrect fail return from tfind in arref.
b3.205  endfile did not detach i/o associated variables.
b3.206  -space with omitted arg. failed
b3.207  looped if dump keyword non-zero after stack
        overflow in garbage collect failure.
b3.208  failure in reading numbers with trailing blanks.
changes
-------
the extensive changes made here mostly result from a
snobol4 implementors meeting held at new york university
in august 1977. they are aimed at
     (1) having spitbol conform to certain snobol4
     language standards  and
     (2) producing a stable definition of minimal by
     carrying out a few essential revisions in the light
     of experience in its use.
changes to spitbol
------------------
c3.201  default values for keywords trim and anchor are
        zero. on systems where records are customarily
        handled without traling blanks, there is no
        obligation to supply such blanks.
c3.202  default value of -inxx control card is -in72.
```

```
c3.203  the second argument of input and output is
        permitted to be an integer as in snobol4.
        in addition input(), output() now give a snobol4
        statement failure if sysio uses the file not
        found return.
        the third argument has a recommended format and
        to override its default delimiter (,) a
        conditional assembly symbol, .ciod, is used.
        interfaces to sysef,sysej,syfc,sysio,sysrw
        are revised.
        wc may now be used to return from sysio, a max
        record length.
c3.204  a new configuration parameter cfp$f (scblk offset
        is introduced. cfp$u is removed.
c3.205  implementation and version identification is
        required - see sysid.
c3.206  routine sysmx returns the maximum length of
        spitbol objects (strings arrays etc).  this
        information is not now needed at time of entry to
        spitbol and hence wc should be zero on entry.
c3.207  a conditional parameter .cnra permits assembly
        of a more compact version with no real
        arithmetic code.
c3.208  terminal is a new pre-associated variable
        capable of performing input and output to an
        online terminal.
        sysri is a new routine used in the implementation
        of this. see also syspp.
c3.209  the environment parameters e$--- are now
        provided by the minimal translator using the
        revised   equ  *   format (see c3.229 and start
        of spitbol definitions section - some reordering
        of symbols has occurred).
c3.210  the interface of sysxi has been slightly revised.
        unavailability of i/o channels after exit(1),
        exit(-1) is documented together with additional
        error return usage for sysin,sysou,syspr,sysrd.
c3.211  spitbol error codes have been frozen - see c3.230
c3.212  the utility routines arref etc. are now
        introduced by rtn statements.
c3.213  sysrl (record length for std input file) is
        removed. since implementation of a general -inxxx
        control card and an ability to specify max record
        length using the third argument of input, sysrl
        has become redundant.
c3.214  sysej and sysxi are now passed a chain linking
        all fcblks in use.
c3.215  a special ending code in sysej is used when
        attempts to use standard output channel fail.
c3.216  restriction c3.233 observed so simplifying
        optimised translation of ent with omitted val.
```

changes to minimal
----

c3.220 minimal opcodes dec, dim, inc, and bmp
are withdrawn and replaced by the more consistent
set dca, dcv, ica, icv.

c3.221 chs has been replaced by the more generally
useful zgb (still likely to be a no-op for most
implementations however).

c3.222 the set of character comparisons has been
reduced to ceq and cne to ease implementation
problems.

c3.223 opcode irz is removed and dvi, rmi orders are
redefined to conform to more common usage.

c3.224 new opcodes ssl and sss are defined. their use
permits return links for n type procedures to be
placed on a local stack if desired.

c3.225 opcode mnz complements zer. it moves a non-zero
flag to its destination.

c3.226 for some machines it is preferable for the stack
to build up rather than down. to permit this
without need for massive changes in minimal and
recoding of existing programs, a scheme has been
devised in which an additional register name, xt,
is used as a synonym for xl when this register
is involved in stack manipulation- see section 4.

c3.227 section 0 of a minimal program is renamed the
procedure section. it now contains, in addition
to exp, specifications of internal procedures
and routines by means of the inp and inr opcodes.

c3.228 the literal operand formats =int and *int have
been withdrawn. =dlbl and *dlbl must be used in
their stead.

c3.229 the format

```
label  equ  *nn
```

used to specify values supplied by the minimal
translator for char. codes etc. is replaced by

```
label  equ  *
```

where the order in which the definitions are
supplied by the translator should match the
order of occurrence in the definitions section.

c3.230 the format of err,erb opcodes is changed to
require a numeric operand.

c3.231 the rtn opcode is used to introduce routines
(which are quite distinct from procedures).

c3.232 conditional assembly directives may be nested.

c3.233 minor restriction placed on the omission of
val with the ent opcode.

```
version 3.1 to 3.2 (aug 77)
---------------------------
bugs fixed
----------
b3.101  astonishing this was unnoticed for three years.
        bad code for snobol4 integer divide, /, gave
        wrong result for operands of opposite signs.
        implementations have either wrongly translated
        dvi and got correct result or correctly
        translated dvi and got wrong result - leeds had
        one of each. see also c3.106.
        test program no. 1 now extended to check /
        more thoroughly.
b3.102  garbage collection bug in scane
changes
-------
c3.101  option to use additional characters ch$ht,ch$vt
        (horizontal and vertical tab) with same syntactic
        significance as ch$bl (blank).
c3.102  option to use a set of shifted case alphabetic
        characters ch$$a ... ch$$$.
c3.103  conditional assembly features are introduced into
        minimal on account of the above.
        see minimal documentation section for details
        of above changes.
c3.104  lch and sch may use an x register first
        operand as alternative to a w register.
c3.105  spitbol statement numbers in the listing may
        optionally be padded to 6 or 8 chars instead of 5
        by defining conditional assembly symbols
        .csn6 or .csn8 .
c3.106  to fix bug 3.101. at moderate cost,
        opcode irz (branch if integer divide remainder
        zero) introduced.
c3.107  to handle possible machine dependency in string
        hashing, chs (complete hashing of string) opcode
        is introduced. probably a no-op on most machines
        - not on the dec10.
c3.108  procedures patin,tfind,trace have been
        modified to conform to the minimal standard
        call and return regime.
c3.109  sysfc interface revised slightly to permit
        osint to return a pointer to a privately
        allocated fcblk which spitbol will return on
        subsequent i/o - see sysfc doc.
c3.110  to remove inconsistencies in calling sequences,
        all sys routines having access to a possible
        fcblk have fcblk ptr or zero in reg. wa on entry.
        change affects sysef, sysen, sysil, sysin,
        sysou, sysrw.
c3.111  syspp bit allocated to provide
         -noexec option on entry to spitbol.
```

```
documentation revisions
-----------------------
d3.101  need to preserve registers in syspi, syspr,
        sysrd calls was overstated.
```

```
version 3.0 to 3.1 (mar 77)
---------------------------
bugs fixed
----------
b3.001  replace() could fail during pre-evaluation.
        spitbol now signals an error for null or
        unequally long 2nd and 3rd arguments.
b3.002  negative second arguments to dupl, lpad, rpad
        caused spitbol to signal an error. now causes
        return of null string or first arg respectively.
b3.003  brn-s used instead of ppm-s in s$sub.
b3.004  err used instead of erb after cmp30.
b3.005  b$pfc, s$cnv, s$def, arith and arref kept
        information illegally above the stack top.
b3.006  pre-evaluation of constant parts of
        complex gotos was erroneous.
b3.007  incorrect handling of labels compiled by code().
b3.008  the single use of trc (in s$rpl) was not in
        accord with its definition. some translations of
        trc may need revision now that the use
        has been brought into line with definition.
changes
-------
a debate on a few weaknesses in minimal design has
been resolved by introducing 4 new opcodes.
c3.001  new minimal opcodes bmp and dim introduced
        to augment inc and dec which are applicable
        only to addresses.
c3.002  the opcode szc (store zero characters) had
        a restricted applicability. it has been
        replaced by the more general zer (zeroise).
c3.003  fcblks may be optionally allocated as xrblk-s or
        xnblk-s  - see sysfc for vital information.
c3.004  control card processing has been recoded.
        -inxxx allows specification of standard input
        file record lengths other than 72 or 80, see also
        sysrl. -sequ is ignored unless -in80 is in effect
c3.005  to enable efficient buffering of chars on
        machines without char. handling orders, the
        csc (complete store characters) instruction
        is introduced. current implementations can
        translate it as a no-op if it is of no benefit.
c3.006  integers 0,1,2 are treated specially.
        icblks in static are used instead of
        allocating space in dynamic.
```

version 2.7 (june 76) to 3.0 (jan 77)
---

bugs fixed
---

b2.701 goes illegal if timed out during processing of dump() call.

b2.702 goes illegal if spitbol error detected in args of code() or eval(). bug fixed so that user now gets a spitbol error report (trappable by setexit) before statement failure.

b2.703 goes illegal in some circumstances when multiple compilation errors occur in a statement

b2.704 goes illegal if garbage collector runs out of stack space.

b2.705 control card processing incorrect for cdc 6400.

b2.706 incorrect handling of multiple occurrences of chars in replace 2nd and 3rd args.

b2.707 stack overflow in pre-evaluation of replace in cdc 6400 version.

b2.708 an explicit call of sysmw was coded in s$dat instead of the mvw opcode.

b2.709 call of garbage collector whilst dumping caused havoc.

b2.710 size restriction on spitbol objects (size must be numerically less than lowest dynamic address) was not enforced, with potential for catastrophe.

b2.711 deferred expressions involving alternation or negation were incorrectly translated.

b2.712 listing of a compilation error at the end of a long line could cause compiler to go illegal.

b2.713 incorrect -nofail code with success goto.

```
changes
-------
(it is not anticipated that major revisions on this
scale will be frequent).
c2.701  default value of anchor keyword is set to 1. this
        conflicts with snobol4 practice but is a
        preferable default for most applications.
c2.702  if errtype is out of range the string in keyword
        errtext is printed as the error message.
c2.703  if stlimit is exceeded, up to 10 more statements
        may be obeyed to permit setexit trap to gain
        control.
c2.704  the concept of an interactive channel is
        introduced for implementations where an online
        terminal may be used for spitbol. the standard
        print file may be specified as interactive in
        which case shorter title lines are output.
        alternatively copies of compilation and
        execution errors only may be sent to this channel
c2.705  printing of compilation statistics may be
        suppressed.
c2.706  printing of execution statistics may be
        suppressed.
c2.707  extended or compact listing format may be
        selected.
c2.708  an initial -nolist option may be specified
        before compilation starts.
c2.709  to specify choices implied by c2.704 to c2.708
        syspp interface is revised and syspi is defined.
c2.710  compilation and execution time statistics
        messages have been shortened.
c2.711  the exit function as in sitbol is introduced
        to permit saving load modules - see sysxi, s$ext.
c2.712  diagnostic routines sysgb and sysgd have been
        removed. they were useful in the early debugging
        days but have fallen into disuse now.
c2.713  szc may have an operand of type opn instead of
        type opw
c2.714  input/output association interface has been
        revised. sysif,sysof have been consolidated into
        the new system routine, sysio, and the
        specification of sysfc has been slightly changed.
c2.715  configuration parameter mxlen has been withdrawn
        and the maximum size of a spitbol object which
        was formerly fixed at spitbol compile time by
        reference to it may now be specified as a run
        time option by placing a value in wc before entry
        to spitbol. (see comment on dynamic area in
        basic information section).
c2.716  a function, host, is introduced which yields
        information about the host machine - see syshs
        and s$hst.
```

```
documentation revisions
-----------------------
d2.701  the description of mvc has been revised to
        reflect the fact that some spitbol code sequences
        rely on mvc not destroying wb. minor changes
        have been made to mwb and mvw descriptions to
        emphasise similarities in the implicit loops of
        these orders.
d2.702  descriptions of dvi and rmi have been clarified.
d2.703  implementation of rsx,lsx,ceq,cge,cgt,chi,clo,clt
        is optional at present since they are currently
        unused. their use in later versions is not
        excluded.
d2.704  impossibility of using stack for return links of
        n type procedures is emphasised.
d2.705  notation (xl),(wc) etc in language description is
        clarified.
d2.706  documentation of sysfc, sysio has been improved.
d2.707  opcode descriptions are cross referenced from
        the alphabetical opcode list.
d2.708  general description of compiler has been moved to
        the start of the compiler proper.
d2.709  definitions of environment parameters have been
        put near the front of the definitions section.
```

minimal–machine independent macro assembly lang.

```
    the following sections describe the implementation
    language originally developed for spitbol but now more
    widely used. minimal is an assembly language
    for an idealized machine. the following describes the
    basic characteristics of this machine.
    section 1 - configuration parameters
    there are several parameters which may vary with the
    target machine. the macro-program is independent of the
    actual definitions of these parameters.
    the definitions of these parameters are supplied by
    the translation program to match the target machine.
    cfp$a                 number of distinct characters in
                          internal alphabet in the range
                          64 le cfp$a le mxlen.
    cfp$b                 number of bytes in a word where a
                          byte is the amount of storage
                          addressed by the least significant
                          address bit.
    cfp$c                 number of characters which can
                          be stored in a single word.
    cfp$f                 byte offset from start of a string
                          block to the first character.
                          depends both on target machine and
                          string data structure. see plc, psc
    cfp$i                 number of words in a signed
                          integer constant
    cfp$l                 the largest unsigned integer
                          of form 2**n - 1 which can be
                          stored in a single word.  n will
                          often be cfp$n but need not be.
    cfp$m                 the largest positive signed integer
                          of form 2**n - 1 which can be
                          stored in a single word.  n will
                          often be cfp$n-1 but need not be.
    cfp$n                 number of bits which can be stored
                          in a one word bit string.
    cfp$r                 number of words in a real constant
    cfp$s                 number of significant digits to
                          be output in conversion of a real
                          quantity.
```
if **.cncr**
else
```
                          the integer consisting of
                          this number of 9s must not be too
                          large to fit in the integer accum.
```
fi
if **.cucf**
```
    cfp$u                 realistic upper bound on alphabet.
```
fi
```
    cfp$x                 number of digits in real exponent
```

```
section 2 - memory
memory is organized into words which each contain cfp$b
bytes. for word machines cfp$b, which is a configuration
parameter, may be one in which case words and bytes are
identical. to each word corresponds an address which is
a non-negative quantity which is a multiple of cfp$b.
data is organized into words as follows.
1)   a signed integer value occupies cfp$i consecutive
     words (cfp$i is a configuration parameter).
     the range may include more negative numbers than
     positive (e.g. the twos complement representation).
2)   a signed real value occupies cfp$r consecutive
     words. (cfp$r is a configuration parameter).
3)   cfp$c characters may be stored in a single word
     (cfp$c is a configuration parameter).
4)   a bit string containing cfp$n bits can be stored in
     a single word (cfp$n is a configuration parameter).
5)   a word can contain a unsigned integer value in
     the range (0 le n le cfp$l). these integer values
     may represent addresses of other words and some of
     the instructions use this fact to provide indexing
     and indirection facilities.
6)   program instructions occupy words in an undefined
     manner. depending on the actual implementation,
     instructions may occupy several words, or part of
     a word, or even be split over word boundaries.
the following regions of memory are available to the
program. each region consists of a series of words with
consecutive addresses.
1)   constant section           assembled constants
2)   working storage section    assembled work areas
3)   program section            assembled instructions
4)   stack area                 allocated stack area
5)   data area                  allocated data area
```

```
section 3 - registers
there are three index registers called xr,xl,xs. in
addition xl may sometimes be referred to by the alias
of xt - see section 4. any of the above registers
may hold a positive unsigned integer in the range
(0 le n le cfp$l). when the index register is used for
indexing purposes, this must be an appropriate address.
xs is special in that it is used to point to the top
item of a stack in memory. the stack may build up or
down in memory.since it is required that xs points to the
stack top but access to items below the top is permitted,
registers xs and xt may be used with suitable offsets
to index stacked items. only xs and xt may be used for
this purpose since the direction of the offset is
target machine dependent. xt is a synonym for xl
which therefore cannot be used in code sequences
referencing xt.
the stack is used for s-r linkage and temporary
data storage for which the stack arrangement is suitable.
xr,xl can also contain a character pointer in conjunction
with the character instructions (see description of plc).
```

```
there are three work registers called wa,wb,wc which
can contain any data item which can be stored in a
single memory word. in fact, the work registers are just
like memory locations except that they have no addresses
and are referenced in a special way by the instructions.
note that registers wa,wb have special uses in connection
with the cvd, cvm, mvc, mvw, mwb, cmc, trc instructions.
register wc may overlap the integer accumulator (ia) in
some implementations. thus any operation changing the
value in wc leaves (ia) undefined and vice versa
except as noted in the following restriction on simple
dump/restore operations.
    restriction
    -----------
if ia and wc overlap then
    sti  iasav
    ldi  iasav
does not change wc, and
    mov  wc,wcsav
    mov  wcsav,wc
does not change ia.
there is an integer accumulator (ia) which is capable of
holding a signed integer value (cfp$i words long).
register wc may overlap the integer accumulator (ia) in
some implementations. thus any operation changing the
value in wc leaves (ia) undefined and vice versa
except as noted in the above restriction on simple
dump/restore operations.
there is a single real accumulator (ra) which can hold
any real value and is completely separate from any of
the other registers or program accessible locations.
the code pointer register (cp) is a special index
register for use in implementations of interpretors.
it is used to contain a pseudo-code pointer and can
only be affected by icp, lcp, scp and lcw instructions.
```

section 4 - the stack
the following notes are to guide both implementors of systems written in minimal and minimal programmers in dealing with stack manipulation. implementation of a downwards building stack is easiest and in general is to be preferred, in which case it is merely necessary to consider xt as an alternative name for xl.
the minimal virtual machine includes a stack and has operand formats -(xs) and (xs)+ for pushing and popping items with an implication that the stack builds down in memory (a d-stack). however on some target machines it is better for the stack to build up (a u-stack).
a stack addressed only by push and pop operations can build in either direction with no complication but such a pure scheme of stack access proves restrictive. hence it is permitted to access buried items using an integer offset past the index register pointing to the stack top. on target machines this offset will be positive/negative for d-stacks/u-stacks and this must be allowed for in the translation.
a further restriction is that at no time may an item be placed above the stack top. for some operations this makes it convenient to advance the stack pointer and then address items below it using a second index register. the problem of signed offsets past such a register then arises. to distinguish stack offsets, which in some implementations may be negative, from non-stack offsets which are invariably positive, xt, an alias or synonym for xl is used. for a u-stack implementation, the minimal translator should negate the sign of offsets applied to both (xs) and (xt).
programmers should note that since xt is not a separate register, xl should not be used in code where xt is referenced. other modifications needed in u-stack translations are in the add, sub, ica, dca opcodes applied to xs, xt. for example

```
minimal           d-stack trans.  u-stack trans.
mov  wa,-(xs)     sbi  xs,1       adi  xs,1
                  sto  wa,(xs)    sto  wa,(xs)
mov  (xt)+,wc     lod  wc,(xl)    lod  wc,(xl)
                  adi  xl,1       sbi  xl,1
add  =seven,xs    adi  xs,7       sbi  xs,7
mov  2(xt),wa     lod  wa,2(xl)   lod  wa,-2(xl)
ica  xs           adi  xs,1       sbi  xs,1
```

note that forms such as

```
mov  -(xs),wa
add  wa,(xs)+
```

are illegal, since they assume information storage above the stack top.

```
section 5 - internal character set
the internal character set is represented by a set of
contiguous codes from 0 to cfp$a-1. the codes for the
digits 0-9 must be contiguous and in sequence. other
than this, there are no restraints.
the following symbols are automatically defined to have
the value of the corresponding internal character code.
ch$la                   letter a
ch$lb                   letter b
.                       .
ch$l$                   letter z
ch$d0                   digit 0
.                       .
ch$d9                   digit 9
ch$am                   ampersand
ch$as                   asterisk
ch$at                   at
ch$bb                   left bracket
ch$bl                   blank
ch$br                   vertical bar
ch$cl                   colon
ch$cm                   comma
ch$dl                   dollar sign
ch$dt                   dot (period)
ch$dq                   double quote
ch$eq                   equal sign
ch$ex                   exclamation mark
ch$mn                   minus
ch$nm                   number sign
ch$nt                   not
ch$pc                   percent
ch$pl                   plus
ch$pp                   left paren
ch$rb                   right bracket
ch$rp                   right paren
ch$qu                   question mark
ch$sl                   slash
ch$sm                   semi-colon
ch$sq                   single quote
ch$un                   underline
the following optional symbols are incorporated
by defining the conditional assembly symbol named.
26 shifted letters incorporated by defining .casl
ch$$a                   shifted a
ch$$b                   shifted b
.                       .
ch$$$                   shifted z
ch$ht                   horizontal tab - define .caht
ch$vt                   vertical tab   - define .cavt
ch$ey                   up arrow       - define .caex
```

```
section 6 - conditional assembly features
some features of the interpreter are applicable to only
certain target machines. they may be incorporated or
omitted by use of conditional assembly. the full
form of a condition is -
.if    conditional assembly symbol    (cas)
.then
       minimal statements1   (ms1)
.else
       minimal statements2   (ms2)
.fi
the following rules apply
1.   the directives .if, .then, .else, .fi must
     start in column 1.
2.   the conditional assembly symbol must start with a
     dot in column 8 followed by 4 letters or digits e.g.
        .ca$1
3.   .then is redundant and may be omitted if wished.
4.   ms1, ms2 are arbitrary sequences of minimal
     statements either of which may be null or may
     contain further conditions.
5.   if ms2 is omitted, .else may also be omitted.
6.   .fi is required.
7.   conditions may be nested to a depth determined
     by the translator (not less than 20, say).
selection of the alternatives ms1, ms2 is by means of the
define and undefine directives of form -
.def   cas
.undef cas
which obey rules 1. and 2. above and may occur at any
point in a minimal program, including within a condition.
multiply defining a symbol is an error.
undefining a symbol which is not defined is not an error.
the effect is that if a symbol is currently defined,
then in any condition depending on it, ms1 will be
processed and ms2 omitted. conversely if it is undefined,
ms1 will be omitted and ms2 processed.
nesting of conditions is such that conditions
in a section not selected for processing must not be
evaluated. nested conditions must remember their
environment whilst being processed. effectively this
implies use of a scheme based on a stack with .if, .fi
matching by the condition processor of the translator.
```

```
section 7 - operand formats
the following section describes the various possibilities
for operands of instructions and assembly operations.
01   int              unsigned integer le cfp$l
02   dlbl             symbol defined in definitions sec
03   wlbl             label in working storage section
04   clbl             label in constant section
05   elbl             program section entry label
06   plbl             program section label (non-entry)
07   x                one of the three index registers
08   w                one of the three work registers
09   (x)              location indexed by x
10   (x)+             like (x) but post increment x
11   -(x)             like (x) but predecrement x
12   int(x)           location int words beyond addr in x
13   dlbl(x)          location dlbl words past addr in x
14   clbl(x)          location (x) bytes beyond clbl
15   wlbl(x)          location (x) bytes beyond wlbl
16   integer          signed integer (dic)
17   real             signed real (drc)
18   =dlbl            location containing dac dlbl
19   *dlbl            location containing dac cfp$b*dlbl
20   =wlbl            location containing dac wlbl
21   =clbl            location containing dac clbl
22   =elbl            location containing dac elbl
23   pnam             procedure label (on prc instruc)
24   eqop             operand for equ instruction
25   ptyp             procedure type (see prc)
26   text             arbitrary text (erb,err,ttl)
27   dtext            delimited text string (dtc)
the numbers in the above list are used in subsequent
description and in some of the minimal translators.
```

```
operand formats (continued)
the following special symbols refer to a collection of
the listed possibilities
val  01,02                      predefined value
     val is used to refer to a predefined one word
     integer value in the range 0 le n le cfp$l.
reg  07,08                      register
     reg is used to describe an operand which can be
     any of the registers (xl,xr,xs,xt,wa,wb,wc). such
     an operand can hold a one word integer (address).
opc  09,10,11                   character
     opc is used to designate a specific character
     operand for use in the lch and sch instructions.
     the index register referenced must be either xr or
     xl (not xs,xt). see section on character operations.
ops  03,04,09,12,13,14,15       memory reference
     ops is used to describe an operand which is in
     memory. the operand may be one or more words long
     depending on the data type. in the case of multiword
     operands, the address given is the first word.
opw  as for ops + 08,10,11      full word
     opw is used to refer to an operand whose capacity is
     that of a full memory word. opw includes all the
     possibilities for ops (the referenced word is used)
     plus the use of one of the three work registers
     (wa,wb,wc). in addition, the formats (x)+ and -(x)
     allow indexed operations in which the index register
     is popped by one word after the reference (x)+,
     or pushed by one word before the reference -(x)
     these latter two formats provide a facility for
     manipulation of stacks. the format does not imply
     a particular direction in which stacks must build -
     it is used for compactness. note that there is a
     restriction which disallows an instruction to use
     an index register in one of these formats
     in some other manner in the same instruction.
     e.g.   mov  xl,(xl)+   is illegal.
     the formats -(x) and (x)+ may also be used in
     pre-decrementation, post-incrementation to access
     the adjacent character of a string.
```

```
operand formats (continued)
opn  as for opw + 07            one word integer
     opn is used to represent an operand location which
     can contain a one word integer (e.g. an address).
     this includes all the possibilities for opw plus
     the use of one of the index registers (xl,xr,xt,
     xs). the range of integer values is 0 le n le cfp$l.
opv  as for opn + 18-22         one word integer value
     opv is used for an operand which can yield a one
     word integer value (e.g. an address). it includes
     all the possibilities for opn (the current value of
     the location is used) plus the use of literals. note
     that although the literal formats are described in
     terms of a reference to a location containing an
     address constant, this location may not actually
     exist in some implementations since only the value
     is required. a restriction is placed on literals
     which may consist only of defined symbols and
     certain labels. consequently small integers to be
     used as literals must be pre-defined, a discipline
     aiding program maintenance and revision.
addr 01,02,03,04,05             address
     addr is used to describe an explicit address value
     (one word integer value) for use with dac.
     ***************************************************
     *   in the following descriptions the usage --     *
     *      (xl),(xr), ... ,(ia)                        *
     *   in the descriptive text signifies the          +
     *   contents of the stated register.              *
     ***************************************************
```

```
section 8 - list of instruction mnemonics
the following list includes all instruction and
assembly operation mnemonics in alphabetical order.
the mnemonics are preceded by a number identifying
the following section where the instruction is described.
a star (*) is appended to the mnemonic if the last
operand may optionally be omitted.
see section -15- for details of statement format and
comment conventions.
 2.1  add  opv,opn      add address
 4.2  adi  ops          add integer
 5.3  adr  ops          add real
 7.1  anb  opw,w        and bit string
 2.17 aov  opv,opn,plbl add address, fail if overflow
 5.16 atn               arctangent of real accum
 2.16 bct  w,plbl       branch and count
 2.5  beq  opn,opv,plbl branch if address equal
 2.18 bev  opn,plbl     branch if address even
 2.8  bge  opn,opv,plbl branch if address greater or equl
 2.7  bgt  opn,opv,plbl branch if address greater
 2.12 bhi  opn,opv,plbl branch if address high
 2.10 ble  opn,opv,plbl branch if address less or equal
 2.11 blo  opn,opv,plbl branch if address low
 2.9  blt  opn,opv,plbl branch if address less than
 2.6  bne  opn,opv,plbl branch if address not equal
 2.13 bnz  opn,plbl     branch if address non-zero
 2.19 bod  opn,plbl     branch if address odd
 1.2  brn  plbl         branch unconditional

```
section 9 - minimal instructions
the following descriptions assume the definitions -
zeroe  equ  0
unity  equ  1
-1-  basic instruction set
1.1  mov  opv,opn     move one word value
     mov causes the value of operand opv to be set as
     the new contents of operand location opn. in the
     case where opn is not an index register, any value
     which can normally occupy a memory word (including
     a part of a multiword real or integer value)
     can be transferred using mov. if the target location
     opn is an index register, then opv must specify an
     appropriate one word value or operand containing
     such an appropriate value.
1.2  brn  plbl        unconditional branch
     brn causes control to be passed to the indicated
     label in the program section.
1.3  bsw  x,val,plbl  branch on switch value
1.4  iff  val,plbl    provide branch for switch
     iff  val,plbl     ...
     ...
     ...
1.5  esw              end of branch switch table
     bsw,iff,esw provide a capability for a switched
     branch similar to a fortran computed goto. the
     val on the bsw instruction is the maximum number
     of branches. the value in x ranges from zero up to
     but not including this maximum. each iff provides a
     branch. val must be less than that given on the bsw
     and control goes to plbl if the value in x matches.
     if the value in x does not correspond to any of the
     iff entries, then control passes to the plbl on the
     bsw. this plbl operand may be omitted if there are
     no values missing from the list.
     iff and esw may only be used in this context.
     execution of bsw may destroy the contents of x.
     the iff entries may be in any order and since
     a translator may thus need to store and sort them,
     the comment field is restricted in length (sec 11).
```

1.6 ent val define program entry point

the symbol appearing in the label field is defined to be a program entry point which can subsequently be used in conjunction with the bri instruction, which provides the only means of entering the code. it is illegal to fall into code identified by an entry point. the entry symbol is assigned an address which need not be a multiple of cfp$b but which must be in the range 0 le cfp$l and the address must not lie within the address range of the allocated data area. furthermore, addresses of successive entry points must be assigned in some ascending sequence so that the address comparison instructions can be used to test the order in which two entry points occur. the symbol val gives an identifying value to the entry point which can be accessed with the lei instruction.

note - subject to the restriction below, val may be omitted if no such identification is needed i.e. if no lei references the entry point. for this case, a translation optimisation is possible in which no memory need be reserved for a null identification which is never to be referenced, but only provided this is done so as not to interfere with the strictly ascending sequence of entry point addresses. to simplify this optimisation for all implementors, the following restriction is observed

> val may only be omitted if the entry point is separated from a following entry point by a non-null minimal code sequence.

entry point addresses are accessible only by use of literals (=elbl, section 7) or dac constants (section 8-11.1).

1.7 bri opn branch indirect

opn contains the address of a program entry point (see ent). control is passed to the executable code starting at the entry point address. opn is left unchanged.

1.8 lei x load entry point identification

x contains the address of an entry point for which an identifying value was given on the the ent line. lei replaces the contents of x by this value.

```
-1-  basic instructions (continued)
1.9  jsr  pnam        call procedure pnam
1.10 ppm  plbl        provide exit parameter
     ppm  plbl         ...
     ...
     ppm  plbl         ...
     jsr causes control to be passed to the named
     procedure. pnam is the label on a prc statement
     elsewhere in the program section (see prc)
     or has been defined using an exp instruction.
     the ppm exit parameters following the call give
     names of program locations (plbl-s) to which
     alternative exi returns of the called procedure may
     pass control. they may optionally be replaced by
     error returns (see err). the number of exit
     parameters following a jsr must equal the int in the
     procedure definition. the operand of ppm may be
     omitted if the corresponding exi return is certain
     not to be taken.
1.11 prc  ptyp,int    define start of procedure
     the symbol appearing in the label field is defined
     to be the name of a procedure for use with jsr.
     a procedure is a contiguous section of instructions
     to which control may be passed with a jsr
     instruction. this is the only way in which the
     instructions in a procedure may be executed. it is
     not permitted to fall into a procedure.
     all procedures should be named in section 0
     inp  statements.
     int is the number of exit parameters (ppm-s) to
     be used in jsr calls.
     there are three possibilities for ptyp, each
     consisting of a single letter as follows.
     r                recursive
     the return point (one or more words) is stored on
     the stack as though one or more mov ...,-(xs)
     instructions were executed.
```

```
-1-  basic instructions (continued)
     n                non-recursive
     the return point is to be stored either
     (1) in a local storage word associated
     with the procedure and not directly
     available to the program in any other manner or
     (2) on a subroutine link stack quite distinct from
     the minimal stack addressed by xs.
     it is an error to use the stack for n-links, since
     procedure parameters or results may be passed via
     the stack.
     if method (2) is used for links, error exits
     (erb,err) from a procedure will necessitate link
     stack resetting. the ssl and sss orders provided
     for this may be regarded as no-ops for
     implementations using method (1).
     e                either
     the return point may be stored in either manner
     according to efficiency requirements of the actual
     physical machine used for the implementation. note
     that programming of e type procedures must be
     independent of the actual implementation.
     the actual form of the return point is undefined.
     however, each word stored on the stack for an
     r-type call must meet the following requirements.
     1)               it can be handled as an address
                      and placed in an index register.
     2)               when used as an operand in an
                      address comparison instruction, it
                      must not appear to lie within
                      the allocated data area.
     3)               it is not required to appear
                      to lie within the program section.
```

```
-1-  basic instructions (continued)
1.12 exi  int         exit from procedure
     the ppm and err parameters following a jsr are
     numbered starting from 1.  exi  int causes control
     to be returned to the int-th such param. exi 1 gives
     control to the plbl of the first ppm after the jsr.
     if int is omitted, control is passed back past the
     last exit parameter (or past the jsr if there are
     none). for r and e type procedures, the
     stack pointer xs must be set to its appropriate
     entry value before executing an exi instruction.
     in this case, exi removes return points from the
     stack if any are stored there so that the stack
     pointer is restored to its calling value.
1.13 enp              define end of procedure body
     enp delimits a procedure body and may not actually
     be executed, hence it must have no label.
1.14 err  int,text    provide error return
     err may replace an exit parameter (ppm) in
     any procedure call. the int argument is a unique
     error code in 0 to 899.
     the text supplied as the other operand is
     arbitrary text in the fortran character set and
     may be used in constructing a file of error
     messages for documenting purposes or for building
     a direct access or other file of messages to be
     used by the error handling code.
     in the event that an exi attempts
     to return control via an exit parameter to
     an err, control is instead passed to the first
     instruction in the error section (which follows the
     program section) with the error code in wa.
1.15 erb  int,text    error branch
     this instruction resembles err except that it may
     occur at any point where a branch is permitted.
     it effects a transfer of control to the error
     section with the error code in wa.
1.16 icv  opn         increment value by one
     icv increments the value of the operand by unity.
     it is equivalent to   add  =unity,opn
1.17 dcv  opn         decrement value by one
     dcv decrements the value of the operand by unity.
     it is equivalent to   sub  =unity,opn
```

```
basic instructions (continued)
1.18 zer  opn         zeroise opn
     zer is equivalent to  mov  =zeroe,opn
1.19 mnz  opn         move non-zero to opn
     any non-zero collectable value may used, for which
     the opcodes bnz/bze will branch/fail to branch.
1.20 ssl  opw         subroutine stack load
1.21 sss  opw         subroutine stack store
     this pair of operations is provided to make possible
     the use of a local stack to hold subroutine (s-r)
     return links for n-type procedures. sss stores the
     s-r stack pointer in opw and ssl loads the s-r
     stack pointer from opw. by using sss in the main
     program or on entry to a procedure which should
     regain control on occurrence of an err or erb and by
     use of ssl in the error processing sections the
     s-r stack pointer can be restored giving a link
     stack cleaned up ready for resumed execution.
     the form of the link stack pointer is undefined in
     minimal (it is likely to be a private register
     known to the translator) and the only requirement
     is that it should fit into a single full word.
     ssl and sss are no-ops if a private link stack is
     not used.
1.22 rtn              define start of routine
     a routine is a code chunk used for similar purposes
     to a procedure. however it is entered by any type of
     conditional or unconditional branch (not by jsr). on
     termination it passes control by a branch (often
     bri through a code word) or even permits control
     to drop through to another routine. no return link
     exists and the end of a routine is not marked by
     an explicit opcode (compare enp).
     all routines should be named in section 0
     inr  statements.
```

```
-2-  operations on one word integer values (addresses)
2.1  add  opv,opn     adds opv to the value in opn and
                      stores the result in opn. undefined
                      if the result exceeds cfp$l.
2.2  sub  opv,opn     subtracts opv from opn. stores the
                      result in opn. undefined if the
                      result is negative.
2.3  ica  opn         increment address in opn
                      equivalent to add *unity,opn
2.4  dca  opn         decrement address in opn
                      equivalent to sub *unity,opn
2.5  beq  opn,opv,plbl branch to plbl if opn eq opv
2.6  bne  opn,opv,plbl branch to plbl if opn ne opv
2.7  bgt  opn,opv,plbl branch to plbl if opn gt opv
2.8  bge  opn,opv,plbl branch to plbl if opn ge opv
2.9  blt  opn,opv,plbl branch to plbl if opn lt opv
2.10 ble  opn,opv,plbl branch to plbl if opn le opv
2.11 blo  opn,opv,plbl equivalent to blt or ble
2.12 bhi  opn,opv,plbl equivalent to bgt or bge
     the above instructions compare two address
     values as unsigned integer values.
     the blo and bhi instructions are used in cases where
     the equal condition either does not occur or can
     result either in a branch or no branch. this avoids
     inefficient translations in some implementations.
2.13 bnz  opn,plbl    equivalent to bne opn,=zeroe,plbl
2.14 bze  opn,plbl    equivalent to beq opn,=zeroe,plbl
2.15 lct  w,opv       load counter for bct
     lct loads a counter value for use with the bct
     instruction. the value in opv is the number of loops
     to be executed. the value in w after this operation
     is an undefined one word integer quantity.
2.16 bct  w,plbl      branch and count
     bct uses the counter value in w to branch the
     required number of times and then finally to fall
     through to the next instruction. bct can only be
     used following an appropriate lct instruction.
     the value in w after execution of bct is undefined.
2.17 aov  opv,opn,plbl add with carry test
     adds opv to the value in opn and stores result in
     opn. branches to plbl if result exceeds cfp$l
     with result in opn undefined. cf. add.
2.18 bev  opn,plbl     branch if even
2.19 bod  opn,plbl     branch if odd
     these operations are used only if .cepp or .crpp is
     defined.  on some implementations, a more efficient
     implementation is possible by noting that address of
     blocks must always be a multiple of cfp$b. we call
     such addresses even.  thus return address on the
     stack (.crpp) and entry point addresses (.cepp) can
     be distinguished from block addresses if they are
     forced to be odd (not a multiple of cfp$b).
     bev and bod branch according as operand is even
```

or odd, respectively.

```
-3-  operations on the code pointer register (cp)
     the code pointer register provides a psuedo
     instruction counter for use in an interpretor. it
     may be implemented as a real register or as a
     memory location, but in either case it is separate
     from any other register. the value in the code
     pointer register is always a word address (i.e.
     a one word integer which is a multiple of cfp$b).
3.1  lcp  reg         load code pointer register
                      this instruction causes the code
                      pointer register to be set from
                      the value in reg which is unchanged
3.2  scp  reg         store code pointer register
                      this instruction loads the current
                      value in the code pointer register
                      into reg. (cp) is unchanged.
3.3  lcw  reg         load next code word
                      this instruction causes the word
                      pointed to by cp to be loaded into
                      the indicated reg. the value in cp
                      is then incremented by one word.
                      execution of lcw may destroy xl.
3.4  icp              increment cp by one word
     on machines with more than three index registers,
     cp can be treated simply as an index register.
     in this case, the following equivalences apply.
     lcp reg is like mov reg,cp
     scp reg is like mov cp,reg
     lcw reg is like mov (cp)+,reg
     icp     is like ica cp
     since lcw is allowed to destroy xl, the following
     implementation using a work location cp$$$ can
     also be used.
     lcp  reg         mov  reg,cp$$$
     scp  reg         mov  cp$$$,reg
     lcw  reg         mov  cp$$$,xl
                      mov  (xl)+,reg
                      mov  xl,cp$$$
     icp              ica  cp$$$
```

```
-4-  operations on signed integer values
4.1  ldi  ops         load integer accumulator from ops
4.2  adi  ops         add ops to integer accumulator
4.3  mli  ops         multiply integer accumulator by ops
4.4  sbi  ops         subtract ops from int accumulator
4.5  dvi  ops         divide integer accumulator by ops
4.6  rmi  ops         set int accum to mod(intacc,ops)
4.7  sti  ops         store integer accumulator at ops
4.8  ngi              negate the value in the integer
                      accumulator (change its sign)
     the equation satisfied by operands and results of
     dvi and rmi is
            div = qot * ops + rem          where
     div = dividend in integer accumulator
     qot = quotient left in ia by div
     ops = the divisor
     rem = remainder left in ia by rmi
     the sign of the result of dvi is + if (ia) and (ops)
     have the same sign and is - if they have opposite
     signs. the sign of (ia) is always used as the sign
     of the result of rem.
     assuming in each case that ia contains the number
     specified in parentheses and that seven and msevn
     hold +7 and -7 resp. the algorithm is illustrated
     below.
     (ia = 13)
     dvi  seven       ia = 1
     rmi  seven       ia = 6
     dvi  msevn       ia = -1
     rmi  msevn       ia = 6
     (ia = -13)
     dvi  seven       ia = -1
     rmi  seven       ia = -6
     dvi  msevn       ia = 1
     rmi  msevn       ia = -6
```

```
     the above instructions operate on a full range of
     signed integer values. with the exception of ldi and
     sti, these instructions may cause integer overflow
     by attempting to produce an undefined or out of
     range result in which case integer overflow is set,
     the result in (ia) is undefined and the following
     instruction must be iov or ino.
     particular care may be needed on target machines
     having distinct overflow and divide by zero
     conditions.
4.9  ino  plbl        jump to plbl if no integer overflow
4.10 iov  plbl        jump to plbl if integer overflow
     these instructions can only occur immediately
     following an instruction which can cause integer
     overflow (adi, sbi, mli, dvi, rmi, ngi) and
     test the result of the preceding instruction.
     iov and ino may not have labels.
4.11 ieq  plbl        jump to plbl if (ia) eq 0
4.12 ige  plbl        jump to plbl if (ia) ge 0
4.13 igt  plbl        jump to plbl if (ia) gt 0
4.14 ile  plbl        jump to plbl if (ia) le 0
4.15 ilt  plbl        jump to plbl if (ia) lt 0
4.16 ine  plbl        jump to plbl if (ia) ne 0
     the above conditional jump instructions do
     not change the contents of the accumulator.
     on a ones complement machine, it is permissible to
     produce negative zero in ia provided these
     instructions operate correctly with such a value.
```

```
    -5-  operations on real values
    5.1  ldr  ops         load real accumulator from ops
    5.2  str  ops         store real accumulator at ops
    5.3  adr  ops         add ops to real accumulator
    5.4  sbr  ops         subtract ops from real accumulator
    5.5  mlr  ops         multiply real accumulator by ops
    5.6  dvr  ops         divide real accumulator by ops
         if the result of any of the above operations causes
         underflow, the result yielded is 0.0.
         if the result of any of the above operations is
         undefined or out of range, real overflow is set,
         the contents of (ra) are undefined and the following
         instruction must be either rov or rno.
         particular care may be needed on target machines
         having distinct overflow and divide by zero
         conditions.
    5.7  rov  plbl        jump to plbl if real overflow
    5.8  rno  plbl        jump to plbl if no real overflow
         these instructions can only occur immediately
         following an instruction which can cause real
         overflow (adr,sbr,mlr,dvr).
    5.9  ngr              negate real accum (change sign)
    5.10 req  plbl        jump to plbl if (ra) eq 0.0
    5.11 rge  plbl        jump to plbl if (ra) ge 0.0
    5.12 rgt  plbl        jump to plbl if (ra) gt 0.0
    5.13 rle  plbl        jump to plbl if (ra) le 0.0
    5.14 rlt  plbl        jump to plbl if (ra) lt 0.0
    5.15 rne  plbl        jump to plbl if (ra) ne 0.0
         the above conditional instructions do not affect
         the value stored in the real accumulator.
         on a ones complement machine, it is permissible to
         produce negative zero in ra provided these
         instructions operate correctly with such a value.
```
if **.cmth**
```
    5.16 atn              arctangent of real accum
    5.17 chp              integer portion of real accum
    5.18 cos              cosine of real accum
    5.19 etx              e to the power in the real accum
    5.20 lnf              natural logorithm of real accum
    5.21 sin              sine of real accum
    5.22 sqr              square root of real accum
    5.23 tan              tangent of real accum
         the above orders operate upon the real accumulator,
         and replace the contents of the accumulator with the
         result.
         if the result of any of the above operations is
         undefined or out of range, real overflow is set,
         the contents of (ra) are undefined and the following
         instruction must be either rov or rno.
```
fi

```
-6-  operations on character values
     character operations employ the concept of a
     character pointer which uses either
     index register xr or xl (not xs).
     a character pointer points to a specific character
     in a string of characters stored cfp$c chars to a
     word. the only operations permitted on a character
     pointer are lch and sch. in particular, a character
     pointer may not even be moved with mov.
        restriction 1.
        --------------
     it is important when coding in minimal to ensure
     that no action occurring between the initial use of
     plc or psc and the eventual clearing of xl or xr on
     completion of character operations can initiate a
     garbage collection. the latter of course could cause
     the addressed characters to be moved leaving the
     character pointers pointing to rubbish.
        restriction 2.
        --------------
     a further restriction to be observed in code
     handling character strings, is that strings built
     dynamically should be right padded with zero
     characters to a full word boundary to permit easy
     hashing and use of ceq or cne in testing strings
     for equality.
6.1  plc  x,opv       prepare ch ptr for lch,cmc,mvc,trc,
                      mcb.
6.2  psc  x,opv       prepare char. ptr for sch,mvc,mcb.
     opv can be omitted if it is zero.
     the char. initially addressed is determined by the
     word address in x and the integer offset opv.
     there is an automatic implied offset of cfp$f bytes.
     cfp$f is used to formally introduce into minimal a
     value needed in translating these opcodes which,
     since minimal itself does not prescribe a string
     structure in detail, depends on the choice of a data
     structure for strings in the minimal program.
     e.g. if cfp$b = cfp$c = 3, cfp$f = 6, num01 = 1, xl
     points to a series of 4 words, abc/def/ghi/jkl, then
         plc  xl,=num01
     points to h.
```

```
-6- operations on character values (continued)
6.3  lch  reg,opc     load character into reg
6.4  sch  reg,opc     store character from reg
     these operations are defined such that the character
     is right justified in register reg with zero bits to
     the left. after lch for example, it is legitimate
     to regard reg as containing the ordinal integer
     corresponding to the character.
     opc is one of the following three possibilities.
     (x)              the character pointed to by the
                      character pointer in x. the
                      character pointer is not changed.
     (x)+             same character as (x) but the
                      character pointer is incremented
                      to point to the next character
                      following execution.
     -(x)             the character pointer is decre-
                      mented before accessing the
                      character so that the previous
                      character is referenced.
6.5  csc  x           complete store characters
     this instruction marks completion of a
     psc,sch,sch,...,sch sequence initiated by
     a  psc  x instruction. no more sch instructions
     using  x  should be obeyed until another psc is
     obeyed. it is provided solely as an efficiency aid
     on machines without character orders since it
     permits use of register buffering of chars in sch
     sequences. where csc is not a no-op, it must observe
     restriction 2. (e.g. in spitbol, alocs zeroises the
     last word of a string frame prior to sch sequence
     being started so csc must not nullify this action.)
     the following instructions are used to compare
     two words containing cfp$c characters.
     comparisons distinct from beq,bne are provided as
     on some target machines, the possibility of the sign
     bit being set may require special action.
     note that restriction 2 above, eases use of these
     orders in testing complete strings for equality,
     since whole word tests are possible.
6.6  ceq  opw,opw,plbl jump to plbl if opw eq opw
6.7  cne  opw,opw,plbl jump to plbl if opw ne opw
```

6.8 cmc plbl,plbl compare characters

cmc is used to compare two character strings. before executing cmc, registers are set up as follows.

(xl) character ptr for first string
(xr) character pointer for second string
(wa) character count (must be .gt. zero)

xl and xr should have been prepared by plc. control passes to first plbl if the first string is lexically less than the second string, and to the second plbl if the first string is lexically greater. control passes to the following instruction if the strings are identical. after executing this instruction, the values of xr and xl are set to zero and the value in (wa) is undefined. arguments to cmc may be complete or partial strings, so making optimisation to use whole word comparisons difficult (dependent in general on shifts and masking).

6.9 trc translate characters

trc is used to translate a character string using a supplied translation table. before executing trc the registers are set as follows.

(xl) char ptr to string to be translated
(xr) char ptr to translate table
(wa) length of string to be translated

xl and xr should have been prepared by plc. the translate table consists of cfp$a contiguous characters giving the translations of the cfp$a characters in the alphabet. on completion, (xr) and (xl) are set to zero and (wa) is undefined.

6.10 flc w fold character to upper case

flc is used only if .culc is defined. the character code value in w is translated to upper case if it corresponds to a lower case character.

```
-7-  operations on bit string values
7.1  anb  opw,w       and bit string values
7.2  orb  opw,w       or bit string values
7.3  xob  opw,w       exclusive or bit string values
     in the above operations, the logical connective is
     applied separately to each of the cfp$n bits.
     the result is stored in the second operand location.
7.4  cmb  w           complement all bits in opw
7.5  rsh  w,val       right shift by val bits
7.6  lsh  w,val       left shift by val bits
7.7  rsx  w,(x)       right shift w number of bits in x
7.8  lsx  w,(x)       left shift w number of bits in x
     the above shifts are logical shifts in which bits
     shifted out are lost and zero bits supplied as
     required. the shift count is in the range 0-cfp$n.
7.9  nzb  w,plbl      jump to plbl if w is not
                      all zero bits.
7.10 zrb  w,plbl      jump to plbl if w is all zero bits
7.11 zgb  opn         zeroise garbage bits
     opn contains a bit string representing a word
     of characters from a string or some function
     formed from such characters (e.g. as a result of
     hashing). on a machine where the word size is not a
     multiple of the character size, some bits in reg may
     be undefined. this opcode replaces such bits by the
     zero bit. zgb is a no-op if the word size is a
     multiple of the character size.
```

```
-8-  conversion instructions
     the following instructions provide for conversion
     between lengths in bytes and lengths in words.
8.1  wtb  reg          convert reg from words to bytes.
                       that is, multiply by cfp$b. this is
                       a no-op if cfp$b is one.
8.2  btw  reg          convert reg from bytes to words
                       by dividing reg by cfp$b discarding
                       the fraction. no-op if cfp$b is one
     the following instructions provide for conversion
     of one word integer values (addresses) to and
     from the full signed integer format.
8.3  mti  opn          the value of opn (an address)
                       is moved as a positive integer
                       to the integer accumulator.
8.4  mfi  opn,plbl     the value currently stored in the
                       integer accumulator is moved
                       to opn as an address if it is in
                       the range 0 to cfp$m inclusive.
                       if the accumulator value is
                       outside this range, then the result
                       in opn is undefined and control is
                       passed to plbl. mfi destroys the
                       value of (ia) whether or not
                       integer overflow is signalled.
                       plbl may be omitted if overflow
                       is impossible.
     the following instructions provide for conversion
     between real values and integer values.
8.5  itr               convert integer value in integer
                       accumulator to real and store in
                       real accumulator (may lose
                       precision in some cases)
8.6  rti  plbl         convert the real value in ra to
                       an integer and place result in ia.
                       conversion is by truncation of the
                       fraction - no rounding occurs.
                       jump to plbl if out of range. (ra)
                       is not changed in either case.
                       plbl may be omitted if overflow
                       is impossible.
```

-8- conversion instructions (continued)

the following instructions provide for computing the length of storage required for a text string.

8.7 ctw w,val — this instruction computes the sum (number of words required to store w characters) + (val). the sum is stored in w. for example, if cfp$c is 5, and wa contains 32, then ctw wa,2 gives a result of 9 in wa.

8.8 ctb w,val — ctb is exactly like ctw except that the result is in bytes. it has the same effect as ctw w,val wtb w

the following instructions provide for conversion from integers to and from numeric digit characters for use in numeric conversion routines. they employ negative integer values to allow for proper conversion of numbers which cannot be complemented.

8.9 cvm plbl — convert by multiplication

the integer accumulator, which is zero or negative, is multiplied by 10. wb contains the character code for a digit. the value of this digit is then subtracted from the result. if the result is out of range, then control is passed to plbl with the result in (ia) undefined. execution of cvm leaves the result in (wb) undefined.

8.10 cvd — convert by division

the integer accumulator, which is zero or negative, is divided by 10. the quotient (zero or negative) is replaced in the accumulator. the remainder is converted to the character code of a digit and placed in wa. for example, an operand of -523 gives a quotient of -52 and a remainder in wa of ch$d3.

```
-9-  block move instructions
the following instructions are used for transferring
data from one area of memory to another in blocks.
they can be implemented with the indicated series of
other macro-instructions, but more efficient imple-
mentations will be possible on most machines.
note that in the equivalent code sequence shown below, a
zero value in wa will move at least one item, and may
may wrap the counter causing a core dump in some imple-
mentations.  thus wa should be .gt. 0 prior to invoking
any of these block move instructions.
9.1  mvc              move characters
     before obeying this order wa,xl,xr should have been
     set up, the latter two by plc, psc resp.
     mvc is equivalent to the sequence
            mov  wb,dumpb
            lct  wa,wa
     loopc  lch  wb,(xl)+
            sch  wb,(xr)+
            bct  wa,loopc
            csc  xr
            mov  dumpb,wb
     the character pointers are bumped as indicated
     and the final value of wa is undefined.
9.2  mvw              move words
     mvw is equivalent to the sequence
     loopw  mov  (xl)+,(xr)+
            dca  wa               wa = bytes to move
            bnz  wa,loopw
     note that this implies that the value in wa is the
     length in bytes which is a multiple of cfp$b.
     the initial addresses in xr,xl are word addresses.
     as indicated, the final xr,xl values point past the
     new and old regions of memory respectively.
     the final value of wa is undefined.
     wa,xl,xr must be set up before obeying mvw.
9.3  mwb              move words backwards
     mwb is equivalent to the sequence
     loopb  mov  -(xl),-(xr)
            dca  wa               wa = bytes to move
            bnz  wa,loopb
     there is a requirement that the initial value in xl
     be at least 256 less than the value in xr. this
     allows an implementation in which chunks of 256
     bytes are moved forward (ibm 360, icl 1900).
     the final value of wa is undefined.
     wa,xl,xr must be set up before obeying mwb.
9.4  mcb              move characters backwards
     mcb is equivalent to the sequence
            mov  wb,dumpb
            lct  wa,wa
     loopc  lch  wb,-(xl)
            sch  wb,-(xr)
```

```
       bct  wa,loopc
       csc  xr
       mov  dumpb,wb
there is a requirement that the initial value in xl
be at least 256 less than the value in xr. this
allows an implementation in which chunks of 256
bytes are moved forward (ibm 360, icl 1900).
the final value of wa is undefined.
wa,xl,xr must be set up before obeying mcb.
```

-10- operations connected with the stack
the stack is an area in memory which is dedicated for use
in conjunction with the stack pointer register (xs). as
previously described, it is used by the jsr and exi
instructions and may be used for storage of any other
data as required.
the stack builds either way in memory and an important
restriction is that the value in (xs) must be the address
of the stack front at all times since
some implementations may randomly destroy stack locations
beyond (xs).
the starting stack base address is passed
in (xs) at the start of execution. during execution it
is necessary to make sure that the stack does not
overflow. this is achieved by executing the following
instruction periodically.
10.1 chk check stack overflow
after successfully executing chk, it is permissible to
use up to 100 additional words before issuing another chk
thus chk need not be issued every time the stack is
expanded. in some implementations, the checking may be
automatic and chk will have no effect. following the
above rule makes sure that the program will operate
correctly in implementations with no automatic check.
if stack overflow occurs (detected either automatically
or by a chk instruction), then control is passed to the
stack overflow section (see program form). note that this
transfer may take place following any instruction which
stores data at a new location on the stack.
after stack overflow, stack is arbitrarily popped
to give some space in which the error procedure may
operate. otherwise a loop of stack overflows may occur.

```
-11- data generation instructions
the following instructions are used to generate constant
values in the constant section and also to assemble
initial values in the working storage section. they
may not appear except in these two sections.
11.1 dac  addr        assemble address constant.
                      generates one word containing the
                      specified one word integer
                      value (address).
11.2 dic  integer     generates an integer value which
                      occupies cfp$i consecutive words.
                      the operand is a digit string with
                      a required leading sign.
11.3 drc  real        assembles a real constant which
                      occupies cfp$r consecutive words.
                      the operand form must obey the
                      rules for a fortran real constant
                      with the extra requirement that a
                      leading sign be present.
11.4 dtc  dtext       define text constant. dtext
                      is started and ended with any
                      character not contained in the
                      characters to be assembled. the
                      constant occupies consecutive words
                      as dictated by the configuration
                      parameter cfp$c. any unused chars
                      in the last word are right filled
                      with zeros (i.e. the character
                      whose internal code is zero).
                      the string contains a sequence of
                      letters, digits, blanks and any of
                      the following special characters.
                      =,$.(*)/+-
                      no other characters
                      may be used in a dtext operand.
11.5 dbc  val         assemble bit string constant. the
                      operand is a positive integer
                      value which is interpreted in
                      binary, right justified and left
                      filled with zero bits. thus 5 would
                      imply the bit string value 00...101.
```

```
-12- symbol definition instructions
the following instruction is used to define symbols
in the definitions section. it may not be used elsewhere.
12.1 equ  eqop        define symbol
     the symbol which appears in the label field is
     defined to have the absolute value given
     by the eqop operand. a given symbol may be defined
     only once in this manner, and any symbols occuring
     in eqop must be previously defined.
     the following are the possibilities for eqop
     val              the indicated value is used
     val+val          the sum of the two values is used.
                      this sum must not exceed cfp$m
     val-val          the difference between the two
                      values (must be positive) is used.
     *                this format defines the label by
                      using a value supplied by the
                      minimal translator. values are
                      required for the
     cfp$x            (configuration parameters)
     e$xxx            (environment parameters)
     ch$xx            (character codes).
                      in order for a translator to
                      handle this format correctly the
                      definitions section must be
                      consulted for details of required
                      symbols as listed at the front of
                      the section.
```

symbol definition instructions (continued)
the following instructions may be used to define symbols
in the procedure section. they may not be used in
any other part of the program.

12.2 exp define external procedure

exp defines the symbol appearing in the label field to be the name of an external procedure which can be referenced in a subsequent jsr instruction. the coding for the procedure is external to the coding of the source program in this language. the code for external procedures may be referred to collectively as the operating system interface, or more briefly, osint, and will frequently be a separately compiled segment of code loaded with spitbol to produce a complete system.

12.3 inp ptyp,int define internal procedure

inp defines the symbol appearing in the label field to be the name of an internal procedure and gives its type and number of exit parameters. the label can be referenced in jsr instructions and it must appear labelling a prc instruction in the program section.

12.4 inr define internal routine

inr defines the symbol appearing in the label field to be the name of an internal routine. the label may be referenced in any type of branch order and it must appear labelling a rtn instruction in the program section.

```
-13- assembly listing layout instructions
13.1 ejc              eject to next page
13.2 ttl  text        set new assembly title
     ttl implies an immediate eject of the
     assembly listing to print the new title.
     the use of ttl and ejc cards is such that the
     program will list neatly if the printer prints
     as many as 58 lines per page. in the event that
     the printer depth is less than this, or if the
     listing contains interspersed lines (such as actual
     generated code), then the format may be upset.
     lines starting with an asterisk are comment lines
     which cause no code to be generated and may occur
     freely anywhere in the program. the format for
     comment lines is given in section -15-.
```

```
-14- program form
     the program consists of separate sections separated
     by sec operations. the sections must appear in the
     following specified order.
14.1 sec              start of procedure section
     (procedure section)
     sec               start of definitions section
     (definitions section)
     sec               start of constant storage section
     (constant storage section)
     sec               start of working storage section
     (working storage section)
     sec               start of program section
     (program section)
     sec               start of stack overflow section
     (stack overflow section)
     sec               start of error section
     (error section)
14.2 end              end of assembly
```

section 10 - program form
procedure section
     the procedure section contains all the exp
     instructions for externally available procedures
     and inp,inr opcodes for internal procedures,routines
     so that a single pass minimal translator has advance
     knowledge of procedure types when translating calls.
definitions section
     the definitions section contains equ instructions
     which define symbols referenced later on in the
     program, constant and work sections.
constant storage section
     the constant storage section consists entirely
     of constants assembled with the dac,dic,drc,dtc,dbc
     assembly operations. these constants can be freely
     referenced by the program instructions.
working storage section
     the working storage section consists entirely of
     dac,dic,drc,dbc,dtc instructions to define a fixed
     length work area. the work locations in this area
     can be directly referenced in program instructions.
     the area is initialized in accordance with the
     values assembled in the instructions.
program section
     the program section contains program instructions
     and associated operations (such as prc, enp, ent).
     control is passed to the first instruction in this
     section when execution is initiated.
stack overflow section
     the stack overflow section contains instructions
     like the program section. control is passed to the
     first instruction in this section following the
     occurrence of stack overflow, see chk instruction.
error section
     the error section contains instructions like the
     program section. control is passed to the first
     instruction in this section when a procedure exit
     corresponds to an error parameter (see err)
     or when an erb opcode is obeyed. the error code
     must clean up the main stack and cater for the
     possibility that a subroutine stack may need clean
     up.

```
osint
     though not part of the minimal source, it is useful
     to refer to the collection of initialisation and
     exp routines as osint (operating system interface).
     errors occurring within osint procedures are
     usually handled by making an error return. if this
     is not feasible or appropriate, osint may use the
     minimal error section to report errors directly by
     branching to it with a suitable numeric error
     code in wa.
```

```
section 11 - statement format
all labels are exactly five characters long and start
with three letters (abcdefghijklmnopqrstuvwxy$) followed
by two letters or digits.
the letter z may not be used in minimal symbols but $ is
permitted.
for implementations where $ may not appear in the
target code , a simple substitution of z for $
may thus be made without risk of producing non-unique
symbols.
the letter z is however permitted in opcode mnemonics and
in comments.
minimal statements are in a fixed format as follows.
cols 1-5              label if any (else blank)
cols 6-7              always blank
cols 8-10             operation mnemonic
cols 11-12            blanks
cols 13-28            operand field, terminated by a
                      blank. may occasionally
                      extend past column 28.
cols 30-64            comment. always separated from the
                      operand field by at least one blank
                      may occasionally start after column
                      30 if the operand extends past 28.
                      a special exception occurs for the
                      iff instruction, whose comment may
                      be only 20 characters long (30-49).
cols 65 on            unused
comment lines have the following format
col 1                 asterisk
cols 2-7              blank
cols 8-64             arbitrary text, restricted to the
                      fortran character set.
the fortran character set is a-z 0-9 =,$.(*)-/+
```

```
section 12 - program execution
execution of the program begins with the first
instruction in the program section.
in addition to the fixed length memory regions defined
by the assembly, there are two dynamically allocated
memory regions as follows.
data area             this is an area available to the
                      program for general storage of data
                      any data value may be stored in
                      this area except instructions.
                      in some implementations, it may be
                      possible to increase the size of
                      this area dynamically by adding
                      words at the top end with a call
                      to a system procedure.
stack area            this region of memory holds
                      the stack used for subroutine calls
                      and other storage of one word
                      integer values (addresses). this
                      is the stack associated with
                      index register xs.
the locations and sizes of these areas are specified
by the values in the registers at the start of program
execution as follows.
(xs)                  address one past the stack base.
                      e.g. if xs is 23456, a d-stack will
                      occupy words 23455,23454,...
                      whereas a u-stack will occupy
                      23457,23458,...
(xr)                  address of the first word
                      in the data area
(xl)                  address of the last word in the
                      data area.
(wa)                  initial stack pointer
(wb,wc,ia,ra,cp)      zero
there is no explicit way to terminate the execution of a
program. this function is performed by an appropriate
system procedure referenced with the sysej instruction.
```

spitbol–basic information

```
general structure
-----------------
this program is a translator for a version of the snobol4
programming language. language details are contained in
the manual macro spitbol by dewar and mccann, technical
report 90, university of leeds 1976.
the implementation is discussed in dewar and mccann,
macro spitbol - a snobol4 compiler, software practice and
experience, 7, 95-113, 1977.
the language is as implemented by the btl translator
(griswold, poage and polonsky, prentice hall, 1971)
with the following principal exceptions.
1)   redefinition of standard system functions and
     operators is not permitted.
2)   the value function is not provided.
3)   access tracing is provided in addition to the
     other standard trace modes.
4)   the keyword stfcount is not provided.
5)   the keyword fullscan is not provided and all pattern
     matching takes place in fullscan mode (i.e. with no
     heuristics applied).
6)   a series of expressions separated by commas may
     be grouped within parentheses to provide a selection
     capability. the semantics are that the selection
     assumes the value of the first expression within it
     which succeeds as they are evaluated from the left.
     if no expression succeeds the entire statement fails
7)   an explicit pattern matching operator is provided.
     this is the binary query (see gimpel sigplan oct 74)
8)   the assignment operator is introduced as in the
     gimpel reference.
9)   the exit function is provided for generating load
     modules - cf. gimpels sitbol.
the method used in this program is to translate the
source code into an internal pseudo-code (see following
section). an interpretor is then used to execute this
generated pseudo-code. the nature of the snobol4 language
is such that the latter task is much more complex than
the actual translation phase. accordingly, nearly all the
code in the program section is concerned with the actual
execution of the snobol4 program.
```

interpretive code format
----
the interpretive pseudo-code consists of a series of
address pointers. the exact format of the code is
described in connection with the cdblk format. the
purpose of this section is to give general insight into
the interpretive approach involved.
the basic form of the code is related to reverse polish.
in other words, the operands precede the operators which
are zero address operators. there are some exceptions to
these rules, notably the unary not operator and the
selection construction which clearly require advance
knowledge of the operator involved.
the operands are moved to the top of the main stack and
the operators are applied to the top stack entries. like
other versions of spitbol, this processor depends on
knowing whether operands are required by name or by value
and moves the appropriate object to the stack. thus no
name/value checks are included in the operator circuits.
the actual pointers in the code point to a block whose
first word is the address of the interpretor routine
to be executed for the code word.
in the case of operators, the pointer is to a word which
contains the address of the operator to be executed. in
the case of operands such as constants, the pointer is to
the operand itself. accordingly, all operands contain
a field which points to the routine to load the value of
the operand onto the stack. in the case of a variable,
there are three such pointers. one to load the value,
one to store the value and a third to jump to the label.
the handling of failure returns deserves special comment.
the location flptr contains the pointer to the location
on the main stack which contains the failure return
which is in the form of a byte offset in the current
code block (cdblk or exblk). when a failure occurs, the
stack is popped as indicated by the setting of flptr and
control is passed to the appropriate location in the
current code block with the stack pointer pointing to the
failure offset on the stack and flptr unchanged.

```
internal data representations
-----------------------------
representation of values
a value is represented by a pointer to a block which
describes the type and particulars of the data value.
in general, a variable is a location containing such a
pointer (although in the case of trace associations this
is modified, see description of trblk).
the following is a list of possible datatypes showing the
type of block used to hold the value. the details of
each block format are given later.
datatype              block type
--------              ----------
array                 arblk or vcblk
code                  cdblk
expression            exblk or seblk
integer               icblk
name                  nmblk
pattern               p0blk or p1blk or p2blk
real                  rcblk
string                scblk
table                 tbblk
program datatype      pdblk
```

```
representation of variables
---------------------------
during the course of evaluating expressions, it is
necessary to generate names of variables (for example
on the left side of a binary equals operator). these are
not to be confused with objects of datatype name which
are in fact values.
from a logical point of view, such names could be simply
represented by a pointer to the appropriate value cell.
however in the case of arrays and program defined
datatypes, this would violate the rule that there must be
no pointers into the middle of a block in dynamic store.
accordingly, a name is always represented by a base and
offset. the base points to the start of the block
containing the variable value and the offset is the
offset within this block in bytes. thus the address
of the actual variable is determined by adding the base
and offset values.
the following are the instances of variables represented
in this manner.
1)   natural variable base is ptr to vrblk
                      offset is *vrval
2)   table element    base is ptr to teblk
                      offset is *teval
3)   array element    base is ptr to arblk
                      offset is offset to element
4)   vector element   base is ptr to vcblk
                      offset is offset to element
5)   prog def dtp     base is ptr to pdblk
                      offset is offset to field value
in addition there are two cases of objects which are
like variables but cannot be handled in this manner.
these are called pseudo-variables and are represented
with a special base pointer as follows=
expression variable   ptr to evblk (see evblk)
keyword variable      ptr to kvblk (see kvblk)
pseudo-variables are handled as special cases by the
access procedure (acess) and the assignment procedure
(asign). see these two procedures for details.
```

```
organization of data area
-------------------------
the data area is divided into two regions.
static area
the static area builds up from the bottom and contains
data areas which are allocated dynamically but are never
deleted or moved around. the macro-program itself
uses the static area for the following.
1)   all variable blocks (vrblk).
2)   the hash table for variable blocks.
3)   miscellaneous buffers and work areas (see program
     initialization section).
in addition, the system procedures may use this area for
input/output buffers, external functions etc. space in
the static region is allocated by calling procedure alost
the following global variables define the current
location and size of the static area.
statb                 address of start of static area
state                 address+1 of last word in area.
the minimum size of static is given approximately by
     12 + *e$hnb + *e$sts + space for alphabet string
     and standard print buffer.
```

```
dynamic area
the dynamic area is built upwards in memory after the
static region. data in this area must all be in standard
block formats so that it can be processed by the garbage
collector (procedure gbcol). gbcol compacts blocks down
in this region as required by space exhaustion and can
also move all blocks up to allow for expansion of the
static region.
with the exception of tables and arrays, no spitbol
object once built in dynamic memory is ever subsequently
modified. observing this rule necessitates a copying
action during string and pattern concatenation.
garbage collection is fundamental to the allocation of
space for values. spitbol uses a very efficient garbage
collector which insists that pointers into dynamic store
should be identifiable without use of bit tables,
marker bits etc. to satisfy this requirement, dynamic
memory must not start at too low an address and lengths
of arrays, tables, strings, code and expression blocks
may not exceed the numerical value of the lowest dynamic
address.
to avoid either penalizing users with modest
requirements or restricting those with greater needs on
host systems where dynamic memory is allocated in low
addresses, the minimum dynamic address may be specified
sufficiently high to permit arbitrarily large spitbol
objects to be created (with the possibility in extreme
cases of wasting large amounts of memory below the
start address). this minimum value is made available
in variable mxlen by a system routine, sysmx.
alternatively sysmx may indicate that a
default may be used in which dynamic is placed
at the lowest possible address following static.
the following global work cells define the location and
length of the dynamic area.
dnamb                   start of dynamic area
dnamp                   next available location
dname                   last available location + 1
dnamb is always higher than state since the alost
procedure maintains some expansion space above state.
*** dnamb must never be permitted to have a value less
than that in mxlen ***
space in the dynamic region is allocated by the alloc
procedure. the dynamic region may be used by system
procedures provided that all the rules are obeyed.
some of the rules are subtle so it is preferable for
osint to manage its own memory needs. spitbol procs
obey rules to ensure that no action can cause a garbage
collection except at such times as contents of xl, xr
and the stack are +clean+ (see comment before utility
procedures and in gbcol for more detail). note
that calls of alost may cause garbage collection (shift
of memory to free space). spitbol procs which call
```

```
system routines assume that they cannot precipitate
collection and this must be respected.
```

```
register usage
--------------
(cp)                code pointer register. used to
                    hold a pointer to the current
                    location in the interpretive pseudo
                    code (i.e. ptr into a cdblk).
(xl,xr)             general index registers. usually
                    used to hold pointers to blocks in
                    dynamic storage. an important
                    restriction is that the value in
                    xl must be collectable for
                    a garbage collect call. a value
                    is collectable if it either points
                    outside the dynamic area, or if it
                    points to the start of a block in
                    the dynamic area.
(xs)                stack pointer. used to point to
                    the stack front. the stack may
                    build up or down and is used
                    to stack subroutine return points
                    and other recursively saved data.
(xt)                an alternative name for xl during
                    its use in accessing stacked items.
(wa,wb,wc)          general work registers. cannot be
                    used for indexing, but may hold
                    various types of data.
(ia)                used for all signed integer
                    arithmetic, both that used by the
                    translator and that arising from
                    use of snobol4 arithmetic operators
(ra)                real accumulator. used for all
                    floating point arithmetic.
```

```
spitbol conditional assembly symbols
------------------------------------
in the spitbol translator, the following conditional
assembly symbols are referred to. to incorporate the
features referred to, the minimal source should be
prefaced by suitable conditional assembly symbol
definitions.
in all cases it is permissible to default the definitions
in which case the additional features will be omitted
from the target code.
.caex                 define to allow up arrow for expon.
.caht                 define to include horizontal tab

this section starts with descriptions of the operating
system dependent procedures which are used by the spitbol
translator. all such procedures have five letter names
beginning with sys. they are listed in alphabetical
order.
all procedures have a  specification consisting of a
model call, preceded by a possibly empty list of register
contents giving parameters available to the procedure and
followed by a possibly empty list of register contents
required on return from the call or which may have had
their contents destroyed. only those registers explicitly
mentioned in the list after the call may have their
values changed.
the segment of code providing the external procedures is
conveniently referred to as osint (operating system
interface). the sysxx procedures it contains provide
facilities not usually available as primitives in
assembly languages. for particular target machines,
implementors may choose for some minimal opcodes which
do not have reasonably direct translations, to use calls
of additional procedures which they provide in osint.
e.g. mwb or trc might be translated as jsr sysmb,
jsr systc in some implementations.
in the descriptions, reference is made to --blk
formats (-- = a pair of letters). see the spitbol
definitions section for detailed descriptions of all
such block formats except fcblk for which sysfc should
be consulted.
section 0 contains inp,inr specifications of internal
procedures,routines. this gives a single pass translator
information making it easy to generate alternative calls
in the translation of jsr-s for procedures of different
types if this proves necessary.
```

sec start of procedures section

if **.csax**

```
    sysax -- after execution
sysax   exp                             define external entry point
    if the conditional assembly symbol .csax is defined,
    this routine is called immediately after execution and
    before printing of execution statistics or dump output.
    purpose of call is for implementor to determine and
    if the call is not required it will be omitted if .csax
    is undefined. in this case sysax need not be coded.
    jsr  sysax            call after execution
```
else
fi

if **.cbsp**

```
    sysbs -- backspace file
sysbs   exp                             define external entry point
    sysbs is used to implement the snobol4 function backspace
    if the conditional assembly symbol .cbsp is defined.
    the meaning is system dependent.  in general, backspace
    repositions the file one record closer to the beginning
    of file, such that a subsequent read or write will
    operate on the previous record.
    (wa)                    ptr to fcblk or zero
    (xr)                    backspace argument (scblk ptr)
    jsr  sysbs              call to backspace
    ppm  loc                return here if file does not exist
    ppm  loc                return here if backspace not allowed
    ppm  loc                return here if i/o error
    (wa,wb)                 destroyed
    the second error return is used for files for which
    backspace is not permitted. for example, it may be expected
    files on character devices are in this category.
```

fi

```
    sysbx -- before execution
```

`sysbx` **exp** define external entry point

```
    called after initial spitbol compilation and before
    commencing execution in case osint needs
    to assign files or perform other necessary services.
    osint may also choose to send a message to online
    terminal (if any) indicating that execution is starting.
    jsr  sysbx            call before execution starts
```

if **.cnci**

```
    sysci -- convert integer
sysci   exp
    sysci is an optional osint routine that causes spitbol to
    call sysci to convert integer values to strings, rather
    than using the internal spitbol conversion code.  this
    code may be less efficient on machines with hardware
    conversion instructions and in such cases, it may be an
    advantage to include sysci.  the symbol .cnci must be
    defined if this routine is to be used.
    the rules for converting integers to strings are that
    positive values are represented without any sign, and
    there are never any leading blanks or zeros, except in
    the case of zero itself which is represented as a single
    zero digit.  negative numbers are represented with a
    preceeding minus sign.  there are never any trailing
    blanks, and conversion cannot fail.
    (ia)                  value to be converted
    jsr  sysci            call to convert integer value
    (xl)                  pointer to pseudo-scblk with string
```

fi
if **.ccmc**

```
    syscm -- general string comparison function
syscm   exp                          define external entry point
    provides string comparison determined by interface.
    used for international string comparison.
    (xr)                 character pointer for first string
    (xl)                 character pointer for second string
    (wb)                 character count of first string
    (wa)                 character count of second string
    jsr  syscm           call to syscm function
    ppm  loc             string too long for syscm
    ppm  loc             first string lexically gt second
    ppm  loc             first string lexically lt second
    ---                  strings equal
    (xl)                 zero
    (xr)                 destroyed
```

fi
if **.cnra**
else
if **.cncr**
```
    syscr -- convert real

    syscr is an optional osint routine that causes spitbol to
    call syscr to convert real values to strings, rather
    than using the internal spitbol conversion code.  this
    code may be desired on machines where the integer size
    is too small to allow production of a sufficient number
    of significant digits.  the symbol .cncr must be defined
    if this routine is to be used.
    the rules for converting reals to strings are that
    positive values are represented without any sign, and
    there are never any leading blanks or zeros, except in
    the case of zero itself which is represented as a single
    zero digit.  negative numbers are represented with a
    preceeding minus sign.  there are never any trailing
    blanks, or trailing zeros in the fractional part.
    conversion cannot fail.
    (ra)                  value to be converted
    (wa)                  no. of significant digits desired
    (wb)                  conversion type:
                           negative for e-type conversion
                           zero for g-type conversion
                           positive for f-type conversion
    (wc)                  character positions in result scblk
    (xr)                  scblk for result
    jsr  syscr            call to convert real value
    (xr)                  result scblk
    (wa)                  number of result characters
```

```
fi
fi
    sysdc -- date check
sysdc   exp                          define external entry point
    sysdc is called to check that the expiry date for a trial
    version of spitbol is unexpired.
    jsr  sysdc            call to check date
    return only if date is ok
```

```
    sysdm  -- dump core
sysdm   exp                              define external entry point
    sysdm is called by a spitbol program call of dump(n) with
    n ge 4.  its purpose is to provide a core dump.
    n could hold an encoding of the start adrs for dump and
    amount to be dumped e.g.  n = 256*a + s , s = start adrs
    in kilowords,  a = kilowords to dump
    (xr)                  parameter n of call dump(n)
    jsr  sysdm            call to enter routine
```

```
    sysdt -- get current date
sysdt   exp                             define external entry point
    sysdt is used to obtain the current date. the date is

    to the operating system in use. it may also contain the
    current time of day. sysdt is used to implement the
    snobol4 function date().
    (xr)                    parameter n of call date(n)
    jsr  sysdt              call to get date
    (xl)                    pointer to block containing date
    the format of the block is like an scblk except that
    the first word need not be set. the result is copied
    into spitbol dynamic memory on return.
```

if **.cera**

```
    sysea -- inform osint of compilation and runtime errors
sysea   exp                             define external entry point
    provides means for interface to take special actions on
    errors
    (wa)                    error code
    (wb)                    line number
    (wc)                    column number
    (xr)                    system stage
if .csfn
    (xl)                    file name (scblk)
fi
    jsr  sysea              call to sysea function
    ppm  loc                suppress printing of error message
    (xr)                    message to print (scblk) or 0
    sysea may not return if interface chooses to retain
    control.  closing files via the fcb chain will be the
    responsibility of the interface.
    all registers preserved
fi
```

```
    sysef -- eject file
sysef   exp                             define external entry point
    sysef is used to write a page eject to a named file. it
    may only be used for files where this concept makes
    sense. note that sysef is not normally used for the
    standard output file (see sysep).
    (wa)                ptr to fcblk or zero
    (xr)                eject argument (scblk ptr)
    jsr  sysef          call to eject file
    ppm  loc            return here if file does not exist
    ppm  loc            return here if inappropriate file
    ppm  loc            return here if i/o error
```

```
    sysej -- end of job
sysej   exp                             define external entry point
    sysej is called once at the end of execution to
    terminate the run. the significance of the abend and
    code values is system dependent. in general, the code
    value should be made available for testing, and the
    abend value should cause some post-mortem action such as
    a dump. note that sysej does not return to its caller.
    see sysxi for details of fcblk chain
    (wa)                  value of abend keyword
    (wb)                  value of code keyword
    (xl)                  o or ptr to head of fcblk chain
    jsr  sysej            call to end job
    the following special values are used as codes in (wb)
    999  execution suppressed
    998  standard output file full or unavailable in a sysxi
         load module. in these cases (wa) contains the number
         of the statement causing premature termination.
```

```
    sysem -- get error message text
sysem   exp                             define external entry point
    sysem is used to obtain the text of err, erb calls in the
    source program given the error code number. it is allowed
    to return a null string if this facility is unavailable.
    (wa)                    error code number
    jsr  sysem              call to get text
    (xr)                    text of message
    the returned value is a pointer to a block in scblk
    format except that the first word need not be set. the
    string is copied into dynamic memory on return.
    if the null string is returned either because sysem does
    not provide error message texts or because wa is out of
    range, spitbol will print the string stored in errtext
    keyword.
```

```
    sysen -- endfile
sysen   exp                             define external entry point
    sysen is used to implement the snobol4 function endfile.
    the meaning is system dependent. in general, endfile
    implies that no further i/o operations will be performed,
    but does not guarantee this to be the case. the file
    should be closed after the call, a subsequent read
    or write may reopen the file at the start or it may be
    necessary to reopen the file via sysio.
    (wa)                    ptr to fcblk or zero
    (xr)                    endfile argument (scblk ptr)
    jsr  sysen              call to endfile
    ppm  loc                return here if file does not exist
    ppm  loc                return here if endfile not allowed
    ppm  loc                return here if i/o error
    (wa,wb)                 destroyed
    the second error return is used for files for which
    endfile is not permitted. for example, it may be expected
    that the standard input and output files are in this
    category.
```

```
    sysep -- eject printer page
sysep   exp                          define external entry point
    sysep is called to perform a page eject on the standard
    printer output file (corresponding to syspr output).
    jsr  sysep            call to eject printer output
```

```
    sysex -- call external function
sysex   exp                          define external entry point
    sysex is called to pass control to an external function
    previously loaded with a call to sysld.
    (xs)                 pointer to arguments on stack
    (xl)                 pointer to control block (efblk)
    (wa)                 number of arguments on stack
    jsr  sysex           call to pass control to function
    ppm  loc             return here if function call fails
    ppm  loc             return here if insufficient memory
    ppm  loc             return here if bad argument type
if .cexp
else
    (xs)                 popped past arguments
fi
    (xr)                 result returned
    the arguments are stored on the stack with
    the last argument at 0(xs). on return, xs
    is popped past the arguments.
    the form of the arguments as passed is that used in the
    spitbol translator (see definitions and data structures
    section). the control block format is also described
    (under efblk) in this section.
    there are two ways of returning a result.
    1)   return a pointer to a block in dynamic storage. this
         block must be in exactly correct format, including
         the first word. only functions written with intimate
         knowledge of the system will return in this way.
    2)   string, integer and real results may be returned by
         pointing to a pseudo-block outside dynamic memory.
         this block is in icblk, rcblk or scblk format except
         that the first word will be overwritten
         by a type word on return and so need not
         be correctly set. such a result is
         copied into main storage before proceeding.
         unconverted results may similarly be returned in a
         pseudo-block which is in correct format including
         type word recognisable by garbage collector since
         block is copied into dynamic memory.
```

```
    sysfc -- file control block routine
sysfc   exp                              define external entry point
    see also sysio
    input and output have 3 arguments referred to as shown
         input(variable name,file arg1,file arg2)
         output(variable name,file arg1,file arg2)
    file arg1 may be an integer or string used to identify
    an i/o channel. it is converted to a string for checking.
    the exact significance of file arg2
    is not rigorously prescribed but to improve portability,
    the scheme described in the spitbol user manual
    should be adopted when possible. the preferred form is
    a string $f$,r$r$,c$c$,i$i$,...,z$z$  where
    $f$ is an optional file name which is placed first.
     remaining items may be omitted or included in any order.
    $r$ is maximum record length
    $c$ is a carriage control character or character string
    $i$ is some form of channel identification used in the
       absence of $f$ to associate the variable
       with a file allocated dynamically by jcl commands at
       spitbol load time.
    ,...,z$z$ are additional fields.
    if , (comma) cannot be used as a delimiter, .ciod
    should be defined to introduce by conditional assembly
    another delimiter (see
      iodel  equ  *
    early in definitions section).
    sysfc is called when a variable is input or output
    associated to check file arg1 and file arg2 and
    to  report whether an fcblk (file control
    block) is necessary and if so what size it should be.
    this makes it possible for spitbol rather than osint to
    allocate such a block in dynamic memory if required
    or alternatively in static memory.
    the significance of an fcblk , if one is requested, is
    entirely up to the system interface. the only restriction
    is that if the fcblk should appear to lie in dynamic
    memory, pointers to it should be proper pointers to
    the start of a recognisable and garbage collectable
    block (this condition will be met if sysfc requests
    spitbol to provide an fcblk).
    an option is provided for osint to return a pointer in
    xl to an fcblk which it privately allocated. this ptr
    will be made available when i/o occurs later.
    private fcblks may have arbitrary contents and spitbol
    stores nothing in them.
```

```
    the requested size for an fcblk in dynamic memory
    should allow a 2 word overhead for block type and
    length fields. information subsequently stored in the
    remaining words may be arbitrary if an xnblk (external
    non-relocatable block) is requested. if the request is
    for an xrblk (external relocatable block) the
    contents of words should be collectable (i.e. any
    apparent pointers into dynamic should be genuine block
    pointers). these restrictions do not apply if an fcblk
    is allocated outside dynamic or is not allocated at all.
    if an fcblk is requested, its fields will be initialised
    to zero before entry to sysio with the exception of
    words 0 and 1 in which the block type and length
    fields are placed for fcblks in dynamic memory only.
    for the possible use of sysej and sysxi, if fcblks
    are used, a chain is built so that they may all be
    found - see sysxi for details.
    if both file arg1 and file arg2 are null, calls of sysfc
    and sysio are omitted.
    if file arg1 is null (standard input/output file), sysfc
    is called to check non-null file arg2 but any request
    for an fcblk will be ignored, since spitbol handles the
    standard files specially and cannot readily keep fcblk
    pointers for them.
    filearg1 is type checked by spitbol so further checking
    may be unneccessary in many implementations.
    file arg2 is passed so that sysfc may analyse and
    check it. however to assist in this, spitbol also passes
    on the stack the components of this argument with
    file name, $f$ (otherwise null) extracted and stacked
    first.
    the other fields, if any, are extracted as substrings,
    pointers to them are stacked and a count of all items
    stacked is placed in wc. if an fcblk was earlier
    allocated and pointed to via file arg1, sysfc is also
    passed a pointer to this fcblk.
    (xl)                  file arg1 scblk ptr (2nd arg)
    (xr)                  filearg2 (3rd arg) or null
    -(xs)...-(xs)         scblks for $f$,$r$,$c$,...
    (wc)                  no. of stacked scblks above
    (wa)                  existing file arg1 fcblk ptr or 0
    (wb)                  0/3 for input/output assocn
    jsr  sysfc            call to check need for fcblk
    ppm  loc              invalid file argument
    ppm  loc              fcblk already in use
    (xs)                  popped (wc) times
    (wa non zero)         byte size of requested fcblk
    (wa=0,xl non zero)    private fcblk ptr in xl
    (wa=xl=0)             no fcblk wanted, no private fcblk
    (wc)                  0/1/2 request alloc of xrblk/xnblk
                          /static block for use as fcblk
    (wb)                  destroyed
```

if **.cgbc**

```
    sysgc -- inform interface of garbage collections
sysgc   exp                          define external entry point
    provides means for interface to take special actions
    prior to and after a garbage collection.
    possible usages-
    1. provide visible screen icon of garbage collection
       in progress
    2. inform virtual memory manager to ignore page access
       patterns during garbage collection.  such accesses
       typically destroy the page working set accumulated
       by the program.
    3. inform virtual memory manager that contents of memory
       freed by garbage collection can be discarded.
    (xr)                 non-zero if beginning gc
                         =0 if completing gc
    (wa)                 dnamb=start of dynamic area
    (wb)                 dnamp=next available location
    (wc)                 dname=last available location + 1
    jsr  sysgc           call to sysgc function
    all registers preserved
fi
```

```
    syshs -- give access to host computer features
syshs   exp                             define external entry point
    provides means for implementing special features
    on different host computers. the only defined entry is
    that where all arguments are null in which case syshs
    returns an scblk containing name of computer,
    name of operating system and name of site separated by
    colons. the scblk need not have a correct first field
    as this is supplied on copying string to dynamic memory.
    spitbol does no argument checking but does provide a
    single error return for arguments checked as erroneous
    by osint. it also provides a single execution error
    return. if these are inadequate, use may be made of the
    minimal error section direct as described in minimal
    documentation, section 10.
    several non-error returns are provided. the first
    corresponds to the defined entry or, for implementation
    defined entries, any string may be returned. the others
    permit respectively,  return a null result, return with a
    result to be stacked which is pointed at by xr, and a
    return causing spitbol statement failure. if a returned
    result is in dynamic memory it must obey garbage
    collector rules. the only results copied on return
    are strings returned via ppm loc3 return.
    (wa)                    argument 1
    (xl)                    argument 2
    (xr)                    argument 3
    (wb)                    argument 4
    (wc)                    argument 5
    jsr  syshs              call to get host information
    ppm  loc1               erroneous arg
    ppm  loc2               execution error
    ppm  loc3               scblk ptr in xl or 0 if unavailable
    ppm  loc4               return a null result
    ppm  loc5               return result in xr
    ppm  loc6               cause statement failure
    ppm  loc7               return string at xl, length wa
    ppm  loc8               return copy of result in xr
```

```
    sysid -- return system identification
sysid   exp                             define external entry point
    this routine should return strings to head the standard
    printer output. the first string will be appended to
    a heading line of the form
         macro spitbol version v.v
    supplied by spitbol itself. v.v are digits giving the
    major version number and generally at least a minor
    version number relating to osint should be supplied to
    give say
         macro spitbol version v.v(m.m)
    the second string should identify at least the machine
    and operating system.  preferably it should include
    the date and time of the run.
    optionally the strings may include site name of the
    the implementor and/or machine on which run takes place,
    unique site or copy number and other information as
    appropriate without making it so long as to be a
    nuisance to users.
    the first words of the scblks pointed at need not be
    correctly set.
    jsr  sysid            call for system identification
    (xr)                  scblk ptr for addition to header
    (xl)                  scblk ptr for second header
```

if **.cinc**

```
    sysif -- switch to new include file
sysif   exp                             define external entry point
    sysif is used for include file processing, both to inform
    the interface when a new include file is desired, and
    when the end of file of an include file has been reached
    and it is desired to return to reading from the previous
    nested file.
    it is the responsibility of sysif to remember the file
    access path to the present input file before switching to
    the new include file.
    (xl)                    ptr to scblk or zero
    (xr)                    ptr to vacant scblk of length cswin
                            (xr not used if xl is zero)
    jsr  sysif              call to change files
    ppm  loc                unable to open file
    (xr)                    scblk with full path name of file
                            (xr not used if input xl is zero)
    register xl points to an scblk containing the name of the
    include file to which the interface should switch.  data
    is fetched from the file upon the next call to sysrd.
    sysif may have the ability to search multiple libraries
    for the include file named in (xl).  it is therefore
    required that the full path name of the file where the
    file was finally located be returned in (xr).  it is this
    name that is recorded along with the source statements,
    and will accompany subsequent error messages.
    register xl is zero to mark conclusion of use of an
    include file.
```

fi

```
    sysil -- get input record length
sysil   exp                             define external entry point
    sysil is used to get the length of the next input record
    from a file previously input associated with a sysio
    call. the length returned is used to establish a buffer
    for a subsequent sysin call.  sysil also indicates to the
    caller if this is a binary or text file.
    (wa)                    ptr to fcblk or zero
    jsr  sysil              call to get record length
    (wa)                    length or zero if file closed
    (wc)                    zero if binary, non-zero if text
    no harm is done if the value returned is too long since
    unused space will be reclaimed after the sysin call.
    note that it is the sysil call (not the sysio call) which
    causes the file to be opened as required for the first
    record input from the file.
```

```
    sysin -- read input record
sysin   exp                             define external entry point
    sysin is used to read a record from the file which was
    referenced in a prior call to sysil (i.e. these calls
    always occur in pairs). the buffer provided is an
    scblk for a string of length set from the sysil call.
    if the actual length read is less than this, the length
    field of the scblk must be modified before returning
    unless buffer is right padded with zeroes.
    it is also permissible to take any of the alternative
    returns after scblk length has been modified.
    (wa)                    ptr to fcblk or zero
    (xr)                    pointer to buffer (scblk ptr)
    jsr  sysin              call to read record
    ppm  loc                endfile or no i/p file after sysxi
    ppm  loc                return here if i/o error
    ppm  loc                return here if record format error
    (wa,wb,wc)              destroyed
```

```
    sysio -- input/output file association
sysio   exp                             define external entry point
    see also sysfc.
    sysio is called in response to a snobol4 input or output
    function call except when file arg1 and file arg2
    are both null.
    its call always follows immediately after a call
    of sysfc. if sysfc requested allocation
    of an fcblk, its address will be in wa.
    for input files, non-zero values of $r$ should be
    copied to wc for use in allocating input buffers. if $r$
    is defaulted or not implemented, wc should be zeroised.
    once a file has been opened, subsequent input(),output()
    calls in which the second argument is identical with that
    in a previous call, merely associate the additional
    variable name (first argument) to the file and do not
    result in re-opening the file.
    in subsequent associated accesses to the file a pointer
    to any fcblk allocated will be made available.
    (xl)                    file arg1 scblk ptr (2nd arg)
    (xr)                    file arg2 scblk ptr (3rd arg)
    (wa)                    fcblk ptr (0 if none)
    (wb)                    0 for input, 3 for output
    jsr  sysio              call to associate file
    ppm  loc                return here if file does not exist
    ppm  loc                return if input/output not allowed
    (xl)                    fcblk pointer (0 if none)
    (wc)                    0 (for default) or max record lngth
    (wa,wb)                 destroyed
    the second error return is used if the file named exists
    but input/output from the file is not allowed. for
    example, the standard output file may be in this category
    as regards input association.
```

```
    sysld -- load external function
sysld   exp                          define external entry point
    sysld is called in response to the use of the snobol4
    load function. the named function is loaded (whatever
    this means), and a pointer is returned. the pointer will
    be used on subsequent calls to the function (see sysex).
    (xr)                 pointer to function name (scblk)
    (xl)                 pointer to library name (scblk)
    jsr  sysld           call to load function
    ppm  loc             return here if func does not exist
    ppm  loc             return here if i/o error
    ppm  loc             return here if insufficient memory
    (xr)                 pointer to loaded code
    the significance of the pointer returned is up to the
    system interface routine. the only restriction is that
    if the pointer is within dynamic storage, it must be
    a proper block pointer.
```

```
    sysmm -- get more memory
sysmm   exp                             define external entry point
    sysmm is called in an attempt to allocate more dynamic
    memory. this memory must be allocated contiguously with
    the current dynamic data area.
    the amount allocated is up to the system to decide. any
    value is acceptable including zero if allocation is
    impossible.
    jsr  sysmm            call to get more memory
    (xr)                  number of additional words obtained
```

```
    sysmx -- supply mxlen
```
sysmx **exp** define external entry point
```
    because of the method of garbage collection, no spitbol
    object is allowed to occupy more bytes of memory than
    the integer giving the lowest address of dynamic
    (garbage collectable) memory. mxlen is the name used to
    refer to this maximum length of an object and for most
    users of most implementations, provided dynamic memory
    starts at an address of at least a few thousand words,
    there is no problem.
    if the default starting address is less than say 10000 or
    20000, then a load time option should be provided where a
    user can request that he be able to create larger
    objects. this routine informs spitbol of this request if
    any. the value returned is either an integer
    representing the desired value of mxlen (and hence the
    minimum dynamic store address which may result in
    non-use of some store) or zero if a default is acceptable
    in which mxlen is set to the lowest address allocated
    to dynamic store before compilation starts.
    if a non-zero value is returned, this is used for keyword
    maxlngth. otherwise the initial low address of dynamic
    memory is used for this keyword.
    jsr  sysmx            call to get mxlen
    (wa)                  either mxlen or 0 for default
```

```
    sysou -- output record
sysou   exp                             define external entry point
    sysou is used to write a record to a file previously
    associated with a sysio call.
    (wa)                    ptr to fcblk
if .csou
                            or 0 for terminal or 1 for output
fi
if .cnbf
    (xr)                    record to be written (scblk)
else
    (xr)                    record to write (bcblk or scblk)
fi
    jsr  sysou              call to output record
    ppm  loc                file full or no file after sysxi
    ppm  loc                return here if i/o error
    (wa,wb,wc)              destroyed
    note that it is the sysou call (not the sysio call) which
    causes the file to be opened as required for the first
    record output to the file.
```

```
    syspi -- print on interactive channel
syspi   exp                             define external entry point
    if spitbol is run from an online terminal, osint can
    request that messages such as copies of compilation
    errors be sent to the terminal (see syspp). if relevant
    reply was made by syspp then syspi is called to send such
    messages to the interactive channel.
    syspi is also used for sending output to the terminal
    through the special variable name, terminal.
    (xr)                    ptr to line buffer (scblk)
    (wa)                    line length
    jsr  syspi              call to print line
    ppm  loc                failure return
    (wa,wb)                 destroyed
```

if **.cpol**

```
    syspl -- provide interactive control of spitbol
syspl   exp                          define external entry point
    provides means for interface to take special actions,
    such as interrupting execution, breakpointing, stepping,
    and expression evaluation.  these last three options are
    not presently implemented by the code calling syspl.
    (wa)                 opcode as follows-
                         =0 poll to allow osint to interrupt
                         =1 breakpoint hit
                         =2 completion of statement stepping
                         =3 expression evaluation result
    (wb)                 statement number
    r$fcb                o or ptr to head of fcblk chain
    jsr  syspl           call to syspl function
    ppm  loc             user interruption
    ppm  loc             step one statement
    ppm  loc             evaluate expression
    ---                  resume execution
                         (wa) = new polling interval
```

fi

```
    syspp -- obtain print parameters
syspp   exp                              define external entry point
    syspp is called once during compilation to obtain
    parameters required for correct printed output format
    and to select other options. it may also be called again
    after sysxi when a load module is resumed. in this
    case the value returned in wa may be less than or equal
    to that returned in initial call but may not be
    greater.
    the information returned is -
    1.   line length in chars for standard print file
    2.   no of lines/page. 0 is preferable for a non-paged
         device (e.g. online terminal) in which case listing
         page throws are suppressed and page headers
         resulting from -title,-stitl lines are kept short.
    3.   an initial -nolist option to suppress listing unless
         the program contains an explicit -list.
    4.   options to suppress listing of compilation and/or
         execution stats (useful for established programs) -
         combined with 3. gives possibility of listing
         file never being opened.
    5.   option to have copies of errors sent to an
         interactive channel in addition to standard printer.
    6.   option to keep page headers short (e.g. if listing
         to an online terminal).
    7.   an option to choose extended or compact listing
         format. in the former a page eject and in the latter
         a few line feeds precede the printing of each
         of-- listing, compilation statistics, execution
         output and execution statistics.
    8.   an option to suppress execution as though a
         -noexecute card were supplied.
    9.   an option to request that name /terminal/  be pre-
         associated to an online terminal via syspi and sysri
    10.  an intermediate (standard) listing option requiring
         that page ejects occur in source listings. redundant
         if extended option chosen but partially extends
         compact option.
    11.  option to suppress sysid identification.
    jsr  syspp            call to get print parameters
    (wa)                  print line length in chars
    (wb)                  number of lines/page
    (wc)                  bits value ...mlkjihgfedcba where
                          a = 1 to send error copy to int.ch.
                          b = 1 means std printer is int. ch.
                          c = 1 for -nolist option
                          d = 1 to suppress compiln. stats
                          e = 1 to suppress execn. stats
                          f = 1/0 for extnded/compact listing
                          g = 1 for -noexecute
                          h = 1 pre-associate /terminal/
                          i = 1 for standard listing option.
                          j = 1 suppresses listing header
```

```
                        k = 1 for -print
                        l = 1 for -noerrors
if .culc
                        m = 1 for -case 1
fi
```

```
    syspr -- print line on standard output file
syspr   exp                             define external entry point
    syspr is used to print a single line on the standard
    output file.
    (xr)                    pointer to line buffer (scblk)
    (wa)                    line length
    jsr  syspr              call to print line
    ppm  loc                too much o/p or no file after sysxi
    (wa,wb)                 destroyed
    the buffer pointed to is the length obtained from the
    syspp call and is filled out with trailing blanks. the
    value in wa is the actual line length which may be less
    than the maximum line length possible. there is no space
    control associated with the line, all lines are printed
    single spaced. note that null lines (wa=0) are possible
    in which case a blank line is to be printed.
    the error exit is used for systems which limit the amount
    of printed output. if possible, printing should be
    permitted after this condition has been signalled once to
    allow for dump and other diagnostic information.
    assuming this to be possible, spitbol may make more syspr
    calls. if the error return occurs another time, execution
    is terminated by a call of sysej with ending code 998.
```

```
    sysrd -- read record from standard input file
sysrd   exp                              define external entry point
    sysrd is used to read a record from the standard input
    file. the buffer provided is an scblk for a string the
    length of which in characters is given in wc, this
    corresponding to the maximum length of string which
    spitbol is prepared to receive. at compile time it
    corresponds to xxx in the most recent -inxxx card
    (default 72) and at execution time to the most recent
    ,r$r$ (record length) in the third arg of an input()
    statement for the standard input file (default 80).
    if fewer than (wc) characters are read, the length
    field of the scblk must be adjusted before returning
    unless the buffer is right padded with zeroes.
    it is also permissible to take the alternative return
    after such an adjustment has been made.
    spitbol may continue to make calls after an endfile
    return so this routine should be prepared to make
    repeated endfile returns.
    (xr)                  pointer to buffer (scblk ptr)
    (wc)                  length of buffer in characters
    jsr  sysrd            call to read line
    ppm  loc              endfile or no i/p file after sysxi
if .csfn
                          or input file name change.  if
                          the former, scblk length is zero.
                          if input file name change, length
                          is non-zero. caller should re-issue
                          sysrd to obtain input record.
fi
    (wa,wb,wc)            destroyed
```

```
    sysri -- read record from interactive channel
sysri   exp                             define external entry point
    reads a record from online terminal for spitbol variable,
    terminal. if online terminal is unavailable then code the
    endfile return only.
    the buffer provided is of length 258 characters. sysri
    should replace the count in the second word of the scblk
    by the actual character count unless buffer is right
    padded with zeroes.
    it is also permissible to take the alternative
    return after adjusting the count.
    the end of file return may be used if this makes
    sense on the target machine (e.g. if there is an
    eof character.)
    (xr)                    ptr to 258 char buffer (scblk ptr)
    jsr  sysri              call to read line from terminal
    ppm  loc                end of file return
    (wa,wb,wc)              may be destroyed
```

```
    sysrw -- rewind file
sysrw   exp                             define external entry point
    sysrw is used to rewind a file i.e. reposition the file
    at the start before the first record. the file should be
    closed and the next read or write call will open the
    file at the start.
    (wa)                ptr to fcblk or zero
    (xr)                rewind arg (scblk ptr)
    jsr  sysrw          call to rewind file
    ppm  loc            return here if file does not exist
    ppm  loc            return here if rewind not allowed
    ppm  loc            return here if i/o error
```

if **.cust**

```
    sysst -- set file pointer
sysst   exp                          define external entry point
    sysst is called to change the position of a file
    pointer. this is accomplished in a system dependent
    manner, and thus the 2nd and 3rd arguments are passed
    unconverted.
    (wa)                 fcblk pointer
    (wb)                 2nd argument
    (wc)                 3rd argument
    jsr  sysst           call to set file pointer
    ppm  loc             return here if invalid 2nd arg
    ppm  loc             return here if invalid 3rd arg
    ppm  loc             return here if file does not exist
    ppm  loc             return here if set not allowed
    ppm  loc             return here if i/o error
```

fi

```
    systm -- get execution time so far
systm   exp                          define external entry point
    systm is used to obtain the amount of execution time
    used so far since spitbol was given control. the units
    are described as milliseconds in the spitbol output, but
    the exact meaning is system dependent. where appropriate,
    this value should relate to processor rather than clock
    timing values.
    if the symbol .ctmd is defined, the units are described
    as deciseconds (0.1 second).
    jsr  systm           call to get timer value
    (ia)                 time so far in milliseconds
                         (deciseconds if .ctmd defined)
```

```
    systt -- trace toggle
systt   exp                          define external entry point
    called by spitbol function trace() with no args to
    toggle the system trace switch.  this permits tracing of
    labels in spitbol code to be turned on or off.
    jsr  systt            call to toggle trace switch
```

```
    sysul -- unload external function
sysul   exp                             define external entry point
    sysul is used to unload a function previously
    loaded with a call to sysld.
    (xr)                    ptr to control block (efblk)
    jsr  sysul              call to unload function
    the function cannot be called following a sysul call
    until another sysld call is made for the same function.
    the efblk contains the function code pointer and also a
    pointer to the vrblk containing the function name (see
    definitions and data structures section).
```

if **.cnex**

else

```
    sysxi -- exit to produce load module
sysxi   exp                              define external entry point
    when sysxi is called, xl contains either a string pointer
    or zero. in the former case, the string gives the
    character name of a program. the intention is that
    spitbol execution should be terminated forthwith and
    the named program loaded and executed. this type of chain
    execution is very system dependent and implementors may
    choose to omit it or find it impossible to provide.
    if (xl) is zero,ia contains one of the following integers
    -1, -2, -3, -4
         create if possible a load module containing only the
         impure area of memory which needs to be loaded with
         a compatible pure segment for subsequent executions.
         version numbers to check compatibility should be
         kept in both segments and checked on loading.
         to assist with this check, (xr) on entry is a
         pointer to an scblk containing the spitbol major
         version number v.v (see sysid).  the file thus
         created is called a save file.
    0    if possible, return control to job control
         command level. the effect if available will be
         system dependent.
    +1, +2, +3, +4
         create if possible a load module from all of
         memory. it should be possible to load and execute
         this module directly.
    in the case of saved load modules, the status of open
    files is not preserved and implementors may choose to
    offer means of attaching files before execution of load
    modules starts or leave it to the user to include
    suitable input(), output() calls in his program.
    sysxi should make a note that no i/o channels,
    including standard files, have files attached so that
    calls of sysin, sysou, syspr, sysrd should fail unless
    new associations are made for the load module.
    at least in the case of the standard output file, it is
    recommended that either the user be required to attach
    a file or that a default file is attached, since the
    problem of error messages generated by the load module
    is otherwise severe. as a last resort, if spitbol
    attempts to write to the standard output file and gets a
    reply indicating that such ouput is unacceptable it stops
    by using an entry to sysej with ending code 998.
    as described below, passing of some arguments makes it
    clear that load module will use a standard output file.
    if use is made of fcblks for i/o association, spitbol
    builds a chain so that those in use may be found in sysxi
    and sysej. the nodes are 4 words long. third word
    contains link to next node or 0, fourth word contains
    fcblk pointer.
```

```
    sysxi (continued)
    (xl)                  zero or scblk ptr to first argument
    (xr)                  ptr to v.v scblk
    (ia)                  signed integer argument
    (wa)                  scblk ptr to second argument
    (wb)                  0 or ptr to head of fcblk chain
    jsr  sysxi            call to exit
    ppm  loc              requested action not possible
    ppm  loc              action caused irrecoverable error
    (wb,wc,ia,xr,xl,cp)   should be preserved over call
    (wa)                  0 in all cases except sucessful
                          performance of exit(4) or exit(-4),
                          in which case 1 should be returned.
    loading and running the load module or returning from
    jcl command level causes execution to resume at the point
    after the error returns which follow the call of sysxi.
    the value passed as exit argument is used to indicate
    options required on resumption of load module.
    +1 or -1 require that on resumption, sysid and syspp be
    called and a heading printed on the standard output file.
    +2 or -2 indicate that syspp will be called but not sysid
    and no heading will be put on standard output file.
    above options have the obvious implication that a
    standard o/p file must be provided for the load module.
    +3, +4, -3 or -4 indicate calls of neither sysid nor
    syspp and no heading will be placed on standard output
    file.
    +4 or -4 indicate that execution is to continue after
    creation of the save file or load module, although all
    files will be closed by the sysxi action.  this permits
    the user to checkpoint long-running programs while
    continuing execution.
    no return from sysxi is possible if another program
    is loaded and entered.

    this section contains all symbol definitions and also
    pictures of all data structures used in the system.
        sec                             start of definitions section
    definitions of machine parameters
    the minimal translator should supply appropriate values
    for the particular target machine for all the
    equ  *
    definitions given at the start of this section.
    note that even if conditional assembly is used to omit
    some feature (e.g. real arithmetic) a full set of cfp$-
    values must be supplied. use dummy values if genuine
    ones are not needed.
cfp$a   equ                     *       number of characters in alphabet
cfp$b   equ                     *       bytes/word addressing factor
cfp$c   equ                     *       number of characters per word
cfp$f   equ                     *       offset in bytes to chars in
                            scblk. see scblk format.
cfp$i   equ                     *       number of words in integer constant
cfp$m   equ                     *       max positive integer in one word
cfp$n   equ                     *       number of bits in one word
    the following definitions require the supply of either
    a single parameter if real arithmetic is omitted or
    three parameters if real arithmetic is included.
if .cnra
nstmx   equ                     *       no. of decimal digits in cfp$m
else
cfp$r   equ                     *       number of words in real constant
cfp$s   equ                     *       number of sig digs for real output
cfp$x   equ                     *       max digits in real exponent

```
    environment parameters
    the spitbol program is essentially independent of
    the definitions of these parameters. however, the
    efficiency of the system may be affected. consequently,
    these parameters may require tuning for a given version
    the values given in comments have been successfully used.
    e$srs is the number of words to reserve at the end of
    storage for end of run processing. it should be
    set as small as possible without causing memory overflow
    in critical situations (e.g. memory overflow termination)
    and should thus reserve sufficient space at least for
    an scblk containing say 30 characters.
e$srs   equ                     *       30 words
    e$sts is the number of words grabbed in a chunk when
    storage is allocated in the static region. the minimum
    permitted value is 256/cfp$b. larger values will lead
    to increased efficiency at the cost of wasting memory.
e$sts   equ                     *       500 words
    e$cbs is the size of code block allocated initially and
    the expansion increment if overflow occurs. if this value
    is too small or too large, excessive garbage collections
    will occur during compilation and memory may be lost
    in the case of a too large value.
e$cbs   equ                     *       500 words
    e$hnb is the number of bucket headers in the variable
    hash table. it should always be odd. larger values will
    speed up compilation and indirect references at the
    expense of additional storage for the hash table itself.
e$hnb   equ                     *       127 bucket headers
    e$hnw is the maximum number of words of a string
    name which participate in the string hash algorithm.
    larger values give a better hash at the expense of taking
    longer to compute the hash. there is some optimal value.
e$hnw   equ                     *       6 words
    e$fsp.  if the amount of free space left after a garbage
    collection is small compared to the total amount of space
    in use garbage collector thrashing is likely to occur as
    this space is used up.  e$fsp is a measure of the
    minimum percentage of dynamic memory left as free space
    before the system routine sysmm is called to try to
    obtain more memory.
e$fsp   equ                     *       15 percent
if .csed
    e$sed.  if the amount of free space left in the sediment
    after a garbage collection is a significant fraction of
    the new sediment size, the sediment is marked for
    collection on the next call to the garbage collector.
e$sed   equ                     *       25 percent

data block formats and definitions
the following sections describe the detailed format of
all possible data blocks in static and dynamic memory.
every block has a name of the form xxblk where xx is a
unique two character identifier. the first word of every
block must contain a pointer to a program location in the
interpretor which is immediately preceded by an address
constant containing the value bl$xx where xx is the block
identifier. this provides a uniform mechanism for
distinguishing between the various block types.
in some cases, the contents of the first word is constant
for a given block type and merely serves as a pointer
to the identifying address constant. however, in other
cases there are several possibilities for the first
word in which case each of the several program entry
points must be preceded by the appropriate constant.
in each block, some of the fields are relocatable. this
means that they may contain a pointer to another block
in the dynamic area. (to be more precise, if they contain
a pointer within the dynamic area, then it is a pointer
to a block). such fields must be modified by the garbage
collector (procedure gbcol) whenever blocks are compacted
in the dynamic region. the garbage collector (actually
procedure gbcpf) requires that all such relocatable
fields in a block must be contiguous.

```
    the description format uses the following scheme.
    1)   block title and two character identifier
    2)   description of basic use of block and indication
         of circumstances under which it is constructed.
    3)   picture of the block format. in these pictures low
         memory addresses are at the top of the page. fixed
         length fields are surrounded by i (letter i). fields
         which are fixed length but whose length is dependent
         on a configuration parameter are surrounded by *
         (asterisk). variable length fields are surrounded
         by / (slash).
    4)   definition of symbolic offsets to fields in
         block and of the size of the block if fixed length
         or of the size of the fixed length fields if the
         block is variable length.
         note that some routines such as gbcpf assume
         certain offsets are equal. the definitions
         given here enforce this.  make changes to
         them only with due care.
    definitions of common offsets
offs1   equ                 *
offs2   equ                 *
offs3   equ                 *
    5)   detailed comments on the significance and formats
         of the various fields.
    the order is alphabetical by identification code.
```

```
    definitions of block codes
    this table provides a unique identification code for
    each separate block type. the first word of a block in
    the dynamic area always contains the address of a program
    entry point. the block code is used as the entry point id
    the order of these codes dictates the order of the table
    used by the datatype function (scnmt in the constant sec)
    block codes for accessible datatypes
    note that real and buffer types are always included, even
    if they are conditionally excluded elsewhere.  this main-
    tains block type codes across all versions of spitbol,
    providing consistancy for external functions.  but note
    that the bcblk is out of alphabetic order, placed at the
    end of the list so as not to change the block type
    ordering in use in existing external functions.
bl$ar   equ                 0       arblk array

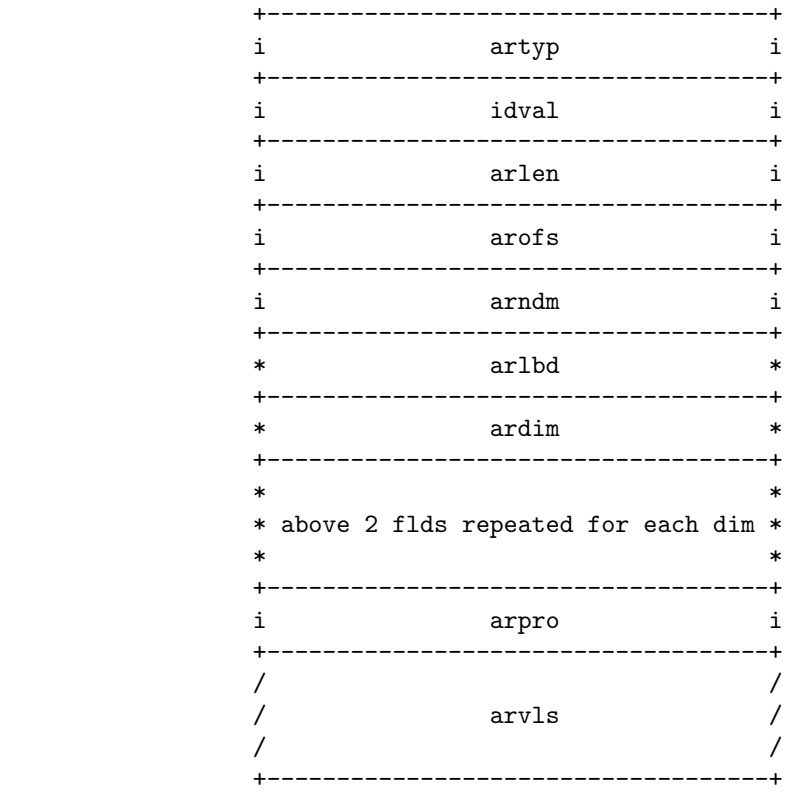
```

```
field references
references to the fields of data blocks are symbolic
(i.e. use the symbolic offsets) with the following
exceptions.
1)   references to the first word are usually not
     symbolic since they use the (x) operand format.
2)   the code which constructs a block is often not
     symbolic and should be changed if the corresponding
     block format is modified.
3)   the plc and psc instructions imply an offset
     corresponding to the definition of cfp$f.
4)   there are non-symbolic references (easily changed)
     in the garbage collector (procedures gbcpf, blkln).
5)   the fields idval, fargs appear in several blocks
     and any changes must be made in parallel to all
     blocks containing the fields. the actual references
     to these fields are symbolic with the above
     listed exceptions.
6)   several spots in the code assume that the
     definitions of the fields vrval, teval, trnxt are
     the same (these are sections of code which search
     out along a trblk chain from a variable).
7)   references to the fields of an array block in the
     array reference routine arref are non-symbolic.
apart from the exceptions listed, references are symbolic
as far as possible and modifying the order or number
of fields will not require changes.
```

```
    common fields for function blocks
    blocks which represent callable functions have two
    common fields at the start of the block as follows.
         +-----------------------------------+
         i                fcode              i
         +-----------------------------------+
         i                fargs              i
         +-----------------------------------+
         /                                   /
         /       rest of function block      /
         /                                   /
         +-----------------------------------+
fcode   equ                  0      pointer to code for function
fargs   equ                  1      number of arguments
    fcode is a pointer to the location in the interpretor
    program which processes this type of function call.
    fargs is the expected number of arguments. the actual
    number of arguments is adjusted to this amount by
    deleting extra arguments or supplying trailing nulls
    for missing ones before transferring though fcode.
    a value of 999 may be used in this field to indicate a
    variable number of arguments (see svblk field svnar).
    the block types which follow this scheme are.
    ffblk                field function
    dfblk                datatype function
    pfblk                program defined function
    efblk                external loaded function
```

```
    identification field
    id   field
    certain program accessible objects (those which contain
    other data values and can be copied) are given a unique
    identification number (see exsid). this id value is an
    address integer value which is always stored in word two.
idval   equ                 1       id value field
    the blocks containing an idval field are.
    arblk               array
```
if **.cnbf**
else
```
    bcblk               buffer control block
```
fi
```
    pdblk               program defined datatype
    tbblk               table
    vcblk               vector block (array)
    note that a zero idval means that the block is only
    half built and should not be dumped (see dumpr).
```

array block (arblk)
an array block represents an array value other than one
with one dimension whose lower bound is one (see vcblk).
an arblk is built with a call to the functions convert
(s$cnv) or array (s$arr).



```
    array block (continued)
artyp   equ                   0       pointer to dummy routine b$art
arlen   equ             idval+1       length of arblk in bytes
arofs   equ             arlen+1       offset in arblk to arpro field
arndm   equ             arofs+1       number of dimensions
arlbd   equ             arndm+1       low bound (first subscript)
ardim   equ         arlbd+cfp$i       dimension (first subscript)
arlb2   equ         ardim+cfp$i       low bound (second subscript)
ardm2   equ         arlb2+cfp$i       dimension (second subscript)
arpro   equ         ardim+cfp$i       array prototype (one dimension)
arvls   equ             arpro+1       start of values (one dimension)
arpr2   equ         ardm2+cfp$i       array prototype (two dimensions)
arvl2   equ             arpr2+1       start of values (two dimensions)
arsi$   equ               arlbd       number of standard fields in block
ardms   equ         arlb2-arlbd       size of info for one set of bounds
    the bounds and dimension fields are signed integer
    values and each occupy cfp$i words in the arblk.
    the length of an arblk in bytes may not exceed mxlen.
    this is required to keep name offsets garbage collectable
    the actual values are arranged in row-wise order and
    can contain a data pointer or a pointer to a trblk.
```

if **.cnbf**

else

```
    buffer control block (bcblk)
    a bcblk is built for every bfblk.
         +-----------------------------------+
         i                bctyp              i
         +-----------------------------------+
         i                idval              i
         +-----------------------------------+
         i                bclen              i
         +-----------------------------------+
         i                bcbuf              i
         +-----------------------------------+
bctyp   equ                   0       ptr to dummy routine b$bct
bclen   equ             idval+1       defined buffer length
bcbuf   equ             bclen+1       ptr to bfblk
bcsi$   equ             bcbuf+1       size of bcblk
    a bcblk is an indirect control header for bfblk.
    the reason for not storing this data directly
    in the related bfblk is so that the bfblk can
    maintain the same skeletal structure as an scblk
    thus facilitating transparent string operations
    (for the most part).  specifically, cfp$f is the
    same for a bfblk as for an scblk.  by convention,
    whereever a buffer value is employed, the bcblk
    is pointed to.
    the corresponding bfblk is pointed to by the
    bcbuf pointer in the bcblk.
    bclen is the current defined size of the character
    array in the bfblk.  characters following the offset
    of bclen are undefined.
```

```
    string buffer block (bfblk)
    a bfblk is built by a call to buffer(...)
         +-----------------------------------+
         i                bftyp              i
         +-----------------------------------+
         i                bfalc              i
         +-----------------------------------+
         /                                   /
         /                bfchr              /
         /                                   /
         +-----------------------------------+
bftyp   equ                   0       ptr to dummy routine b$bft
bfalc   equ             bftyp+1       allocated size of buffer
bfchr   equ             bfalc+1       characters of string
bfsi$   equ               bfchr       size of standard fields in bfblk
    the characters in the buffer are stored left justified.
    the final word of defined characters is always zero
    (character) padded.  any trailing allocation past the
    word containing the last character contains
    unpredictable contents and is never referenced.
    note that the offset to the characters of the string
    is given by cfp$f, as with an scblk.  however, the
    offset which is occupied by the length for an scblk
    is the total char space for bfblks, and routines which
    deal with both must account for this difference.
    the value of bfalc may not exceed mxlen.  the value of
    bclen is always less than or equal to bfalc.
```
fi

```
    code construction block (ccblk)
    at any one moment there is at most one ccblk into
    which the compiler is currently storing code (cdwrd).
         +-----------------------------------+
         i                cctyp              i
         +-----------------------------------+

```
    cdstm is the statement number of the current statement.
    cdjmp, cdfal are set as follows.
    1)   if the failure exit is the next statement
         cdjmp = b$cds
         cdfal = ptr to cdblk for next statement
    2)   if the failure exit is a simple label name
         cdjmp = b$cds
         cdfal is a ptr to the vrtra field of the vrblk
    3)   if there is no failure exit (-nofail mode)
         cdjmp = b$cds
         cdfal = o$unf
    4)   if the failure exit is complex or direct
         cdjmp = b$cdc
         cdfal is the offset to the o$gof word
```

```
code block (continued)
cdcod is the start of the actual code. first we describe
the code generated for an expression. in an expression,
elements are fetched by name or by value. for example,
the binary equal operator fetches its left argument
by name and its right argument by value. these two
cases generate quite different code and are described
separately. first we consider the code by value case.
generation of code by value for expressions elements.
expression            pointer to exblk or seblk
integer constant      pointer to icblk
null constant         pointer to nulls
pattern               (resulting from preevaluation)
                      =o$lpt
                      pointer to p0blk,p1blk or p2blk
real constant         pointer to rcblk

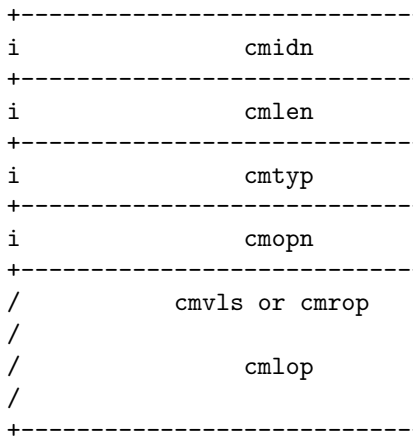
generation of a word containing the address of another
word which contains the entry point address o$xxx.
```

```
code block (continued)
now we consider the overall structure of the code block
for a statement with possible goto fields.
first comes the code for the statement body.
the statement body is an expression to be evaluated
by value although the value is not actually required.
normal value code is generated for the body of the
statement except in the case of a pattern match by
value, in which case the following is generated.
                      value code for left operand
                      value code for right operand
                      =o$pms
next we have the code for the success goto. there are
several cases as follows.
1)   no success goto  ptr to cdblk for next statement
2)   simple label     ptr to vrtra field of vrblk
3)   complex goto     (code by name for goto operand)
                      =o$goc
4)   direct goto      (code by value for goto operand)
                      =o$god
following this we generate code for the failure goto if
it is direct or if it is complex, simple failure gotos
having been handled by an appropriate setting of the
cdfal field of the cdblk. the generated code is one
of the following.
1)   complex fgoto    =o$fif
                      =o$gof
                      name code for goto operand
                      =o$goc
2)   direct fgoto     =o$fif
                      =o$gof
                      value code for goto operand
                      =o$god
an optimization occurs if the success and failure gotos
are identical and either complex or direct. in this case,
no code is generated for the success goto and control
is allowed to fall into the failure goto on success.
```

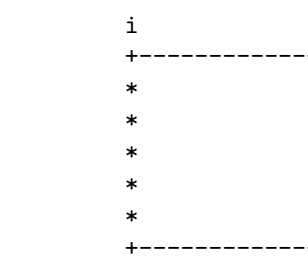
```
    compiler block (cmblk)
    a compiler block (cmblk) is built by expan to represent
    one node of a tree structured expression representation.
```



```
cmidn   equ                 0       pointer to dummy routine b$cmt
cmlen   equ           cmidn+1       length of cmblk in bytes
cmtyp   equ           cmlen+1       type (c$xxx, see list below)
cmopn   equ           cmtyp+1       operand pointer (see below)
cmvls   equ           cmopn+1       operand value pointers (see below)
cmrop   equ             cmvls       right (only) operator operand
cmlop   equ           cmvls+1       left operator operand
cmsi$   equ             cmvls       number of standard fields in cmblk
cmus$   equ           cmsi$+1       size of unary operator cmblk
cmbs$   equ           cmsi$+2       size of binary operator cmblk
cmar1   equ           cmvls+1       array subscript pointers
    the cmopn and cmvls fields are set as follows
    array reference       cmopn = ptr to array operand
                          cmvls = ptrs to subscript operands
    function call         cmopn = ptr to vrblk for function
                          cmvls = ptrs to argument operands
    selection             cmopn = zero
                          cmvls = ptrs to alternate operands
    unary operator        cmopn = ptr to operator dvblk
                          cmrop = ptr to operand
    binary operator       cmopn = ptr to operator dvblk
                          cmrop = ptr to right operand
                          cmlop = ptr to left operand
```

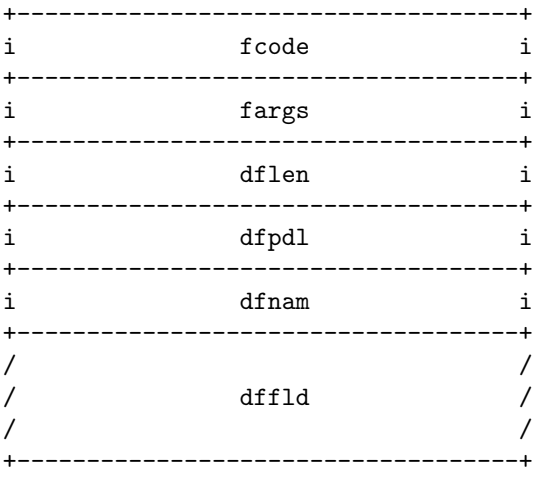
```
    cmtyp is set to indicate the type of expression element
    as shown by the following table of definitions.
c$arr   equ                   0       array reference
c$fnc   equ             c$arr+1       function call
c$def   equ             c$fnc+1       deferred expression (unary *)
c$ind   equ             c$def+1       indirection (unary $)
c$key   equ             c$ind+1       keyword reference (unary ampersand)
c$ubo   equ             c$key+1       undefined binary operator
c$uuo   equ             c$ubo+1       undefined unary operator
c$uo$   equ             c$uuo+1       test value (=c$uuo+1=c$ubo+2)
c$$nm   equ             c$uuo+1       number of codes for name operands
    the remaining types indicate expression elements which
    can only be evaluated by value (not by name).
c$bvl   equ             c$uuo+1       binary op with value operands
c$uvl   equ             c$bvl+1       unary operator with value operand
c$alt   equ             c$uvl+1       alternation (binary bar)
c$cnc   equ             c$alt+1       concatenation
c$cnp   equ             c$cnc+1       concatenation, not pattern match
c$unm   equ             c$cnp+1       unary op with name operand
c$bvn   equ             c$unm+1       binary op (operands by value, name)
c$ass   equ             c$bvn+1       assignment
c$int   equ             c$ass+1       interrogation
c$neg   equ             c$int+1       negation (unary not)
c$sel   equ             c$neg+1       selection
c$pmt   equ             c$sel+1       pattern match
c$pr$   equ               c$bvn       last preevaluable code
c$$nv   equ             c$pmt+1       number of different cmblk types
```

```
    character table block (ctblk)
    a character table block is used to hold logical character
    tables for use with any,notany,span,break,breakx
    patterns. each character table can be used to store
    cfp$n distinct tables as bit columns. a bit column
    allocated for each argument of more than one character
    in length to one of the above listed pattern primitives.
```



```
cttyp   equ                   0       pointer to dummy routine b$ctt
ctchs   equ             cttyp+1       start of character table words
ctsi$   equ         ctchs+cfp$a       number of words in ctblk
    ctchs is cfp$a words long and consists of a one word
    bit string value for each possible character in the
    internal alphabet. each of the cfp$n possible bits in
    a bitstring is used to form a column of bit indicators.
    a bit is set on if the character is in the table and off
    if the character is not present.
```

```
    datatype function block (dfblk)
    a datatype function is used to control the construction
    of a program defined datatype object. a call to the
    system function data builds a dfblk for the datatype name
    note that these blocks are built in static because pdblk
    length is got from dflen field.  if dfblk was in dynamic
    store this would cause trouble during pass two of garbage
    collection.  scblk referred to by dfnam field is also put
    in static so that there are no reloc. fields. this cuts
    garbage collection task appreciably for pdblks which are
    likely to be present in large numbers.
```



```
dflen   equ             fargs+1       length of dfblk in bytes
dfpdl   equ             dflen+1       length of corresponding pdblk
dfnam   equ             dfpdl+1       pointer to scblk for datatype name
dffld   equ             dfnam+1       start of vrblk ptrs for field names
dfflb   equ             dffld-1       offset behind dffld for field func
dfsi$   equ               dffld       number of standard fields in dfblk
    the fcode field points to the routine b$dfc
    fargs (the number of arguments) is the number of fields.
```

```
    dope vector block (dvblk)
    a dope vector is assembled for each possible operator in
    the snobol4 language as part of the constant section.
         +-----------------------------------+
         i                dvopn              i
         +-----------------------------------+
         i                dvtyp              i
         +-----------------------------------+
         i                dvlpr              i
         +-----------------------------------+
         i                dvrpr              i
         +-----------------------------------+
dvopn   equ                   0       entry address (ptr to o$xxx)
dvtyp   equ             dvopn+1       type code (c$xxx, see cmblk)
dvlpr   equ             dvtyp+1       left precedence (llxxx, see below)
dvrpr   equ             dvlpr+1       right precedence (rrxxx, see below)
dvus$   equ             dvlpr+1       size of unary operator dv
dvbs$   equ             dvrpr+1       size of binary operator dv
dvubs   equ         dvus$+dvbs$       size of unop + binop (see scane)
    the contents of the dvtyp field is copied into the cmtyp
    field of the cmblk for the operator if it is used.
    the cmopn field of an operator cmblk points to the dvblk
    itself, providing the required entry address pointer ptr.
    for normally undefined operators, the dvopn (and cmopn)
    fields contain a word offset from r$uba of the function
    block pointer for the operator (instead of o$xxx ptr).
    for certain special operators, the dvopn field is not
    required at all and is assembled as zero.
    the left precedence is used in comparing an operator to
    the left of some other operator. it therefore governs the
    precedence of the operator towards its right operand.
    the right precedence is used in comparing an operator to
    the right of some other operator. it therefore governs
    the precedence of the operator towards its left operand.
    higher precedence values correspond to a tighter binding
    capability. thus we have the left precedence lower
    (higher) than the right precedence for right (left)
    associative binary operators.
    the left precedence of unary operators is set to an
    arbitrary high value. the right value is not required and
    consequently the dvrpr field is omitted for unary ops.
```

```
    table of operator precedence values
rrass   equ                  10      right equal
llass   equ                  00      left equal
rrpmt   equ                  20      right question mark
llpmt   equ                  30      left question mark
rramp   equ                  40      right ampersand
llamp   equ                  50      left ampersand

rrdld   equ                 240      right dollar, dot
lldld   equ                 250      left dollar, dot
rrnot   equ                 270      right not
llnot   equ                 260      left not
lluno   equ                 999      left all unary operators
    precedences are the same as in btl snobol4 with the
    following exceptions.
    1)   binary question mark is lowered and made left assoc-
         iative to reflect its new use for pattern matching.
    2)   alternation and concatenation are made right
         associative for greater efficiency in pattern
         construction and matching respectively. this change
         is transparent to the snobol4 programmer.
    3)   the equal sign has been added as a low precedence
         operator which is right associative to reflect its
         more general usage in this version of snobol4.
```

```
    external function block (efblk)
    an external function block is used to control the calling
    of an external function. it is built by a call to load.
         +-----------------------------------+

```

```
    expression variable block (evblk)
    in this version of spitbol, an expression can be used in
    any position which would normally expect a name (for
    example on the left side of equals or as the right
    argument of binary dot). this corresponds to the creation
    of a pseudo-variable which is represented by a pointer to
    an expression variable block as follows.
         +-----------------------------------+
         i                evtyp              i
         +-----------------------------------+
         i                evexp              i
         +-----------------------------------+
         i                evvar              i
         +-----------------------------------+
evtyp   equ                   0       pointer to dummy routine b$evt
evexp   equ             evtyp+1       pointer to exblk for expression
evvar   equ             evexp+1       pointer to trbev dummy trblk
evsi$   equ             evvar+1       size of evblk
    the name of an expression variable is represented by a
    base pointer to the evblk and an offset of evvar. this
    value appears to be trapped by the dummy trbev block.
    note that there is no need to allow for the case of an
    expression variable which references an seblk since a
    variable which is of the form *var is equivalent to var.
```

```
    expression block (exblk)
    an expression block is built for each expression
    referenced in a program or created by eval or convert
    during execution of a program.
         +-----------------------------------+
         i                extyp              i
         +-----------------------------------+
         i                exstm              i
```
if **.csln**
```
         +-----------------------------------+
         i                exsln              i
```
fi
```
         +-----------------------------------+
         i                exlen              i
         +-----------------------------------+
         i                exflc              i
         +-----------------------------------+
         /                                   /
         /                excod              /
         /                                   /
         +-----------------------------------+
```
```
extyp   equ                  0      ptr to routine b$exl to load expr
exstm   equ                cdstm    stores stmnt no. during evaluation
```
if **.csln**
```
exsln   equ              exstm+1    stores line no. during evaluation
exlen   equ              exsln+1    length of exblk in bytes
```
else
```
exlen   equ              exstm+1    length of exblk in bytes
```
fi
```
exflc   equ              exlen+1    failure code (=o$fex)
excod   equ              exflc+1    pseudo-code for expression
exsi$   equ                excod    number of standard fields in exblk
    there are two cases for excod depending on whether the
    expression can be evaluated by name (see description
    of cdblk for details of code for expressions).
    if the expression can be evaluated by name we have.
                         (code for expr by name)
                         =o$rnm
    if the expression can only be evaluated by value.
                         (code for expr by value)
                         =o$rvl
```

```
    field function block (ffblk)
    a field function block is used to control the selection
    of a field from a program defined datatype block.
    a call to data creates an ffblk for each field.
         +-----------------------------------+
         i                fcode              i
         +-----------------------------------+
         i                fargs              i
         +-----------------------------------+
         i                ffdfp              i
         +-----------------------------------+
         i                ffnxt              i
         +-----------------------------------+
         i                ffofs              i
         +-----------------------------------+
ffdfp   equ             fargs+1       pointer to associated dfblk
ffnxt   equ             ffdfp+1       ptr to next ffblk on chain or zero
ffofs   equ             ffnxt+1       offset (bytes) to field in pdblk
ffsi$   equ             ffofs+1       size of ffblk in words
    the fcode field points to the routine b$ffc.
    fargs always contains one.
    ffdfp is used to verify that the correct program defined
    datatype is being accessed by this call.
    ffdfp is non-reloc. because dfblk is in static
    ffofs is used to select the appropriate field. note that
    it is an actual offset (not a field number)
    ffnxt is used to point to the next ffblk of the same name
    in the case where there are several fields of the same
    name for different datatypes. zero marks the end of chain
```

```
    integer constant block (icblk)
    an icblk is created for every integer referenced or
    created by a program. note however that certain internal
    integer values are stored as addresses (e.g. the length
    field in a string constant block)
         +-----------------------------------+
         i                icget              i
         +-----------------------------------+
         *                icval              *
         +-----------------------------------+
icget   equ                   0      ptr to routine b$icl to load int
icval   equ             icget+1      integer value
icsi$   equ         icval+cfp$i      size of icblk
    the length of the icval field is cfp$i.
```

```
    keyword variable block (kvblk)
    a kvblk is used to represent a keyword pseudo-variable.
    a kvblk is built for each keyword reference (kwnam).
         +-----------------------------------+
         i                kvtyp              i
         +-----------------------------------+
         i                kvvar              i
         +-----------------------------------+
         i                kvnum              i
         +-----------------------------------+
```

```
kvtyp   equ                  0       pointer to dummy routine b$kvt
kvvar   equ            kvtyp+1       pointer to dummy block trbkv
kvnum   equ            kvvar+1       keyword number
kvsi$   equ            kvnum+1       size of kvblk
```

```
    the name of a keyword variable is represented by a
    base pointer to the kvblk and an offset of kvvar. the
    value appears to be trapped by the pointer to trbkv.
```

```
    name block (nmblk)
    a name block is used wherever a name must be stored as
    a value following use of the unary dot operator.
         +-----------------------------------+
         i                nmtyp              i
         +-----------------------------------+
         i                nmbas              i
         +-----------------------------------+
         i                nmofs              i
         +-----------------------------------+
nmtyp   equ                   0       ptr to routine b$nml to load name
nmbas   equ              nmtyp+1      base pointer for variable
nmofs   equ              nmbas+1      offset for variable
nmsi$   equ              nmofs+1      size of nmblk
    the actual field representing the contents of the name
    is found nmofs bytes past the address in nmbas.
    the name is split into base and offset form to avoid
    creation of a pointer into the middle of a block which
    could not be handled properly by the garbage collector.
    a name may be built for any variable (see section on
    representations of variables) this includes the
    cases of pseudo-variables.
```

```
    pattern block, no parameters (p0blk)
    a p0blk is used to represent pattern nodes which do
    not require the use of any parameter values.
         +-----------------------------------+
         i                pcode              i
         +-----------------------------------+
         i                pthen              i
         +-----------------------------------+
pcode   equ                   0      ptr to match routine (p$xxx)
pthen   equ             pcode+1      pointer to subsequent node
pasi$   equ             pthen+1      size of p0blk
    pthen points to the pattern block for the subsequent
    node to be matched. this is a pointer to the pattern
    block ndnth if there is no subsequent (end of pattern)
    pcode is a pointer to the match routine for the node.
```

```
    pattern block (one parameter)
    a p1blk is used to represent pattern nodes which
    require one parameter value.
         +-----------------------------------+
         i                pcode              i
         +-----------------------------------+
         i                pthen              i
         +-----------------------------------+
         i                parm1              i
         +-----------------------------------+
parm1   equ             pthen+1       first parameter value
pbsi$   equ             parm1+1       size of p1blk in words
    see p0blk for definitions of pcode, pthen
    parm1 contains a parameter value used in matching the
    node. for example, in a len pattern, it is the integer
    argument to len. the details of the use of the parameter
    field are included in the description of the individual
    match routines. parm1 is always an address pointer which
    is processed by the garbage collector.
```

```
    pattern block (two parameters)
    a p2blk is used to represent pattern nodes which
    require two parameter values.
         +-----------------------------------+
         i                pcode              i
         +-----------------------------------+
         i                pthen              i
         +-----------------------------------+
         i                parm1              i
         +-----------------------------------+
         i                parm2              i
         +-----------------------------------+
parm2   equ             parm1+1       second parameter value
pcsi$   equ             parm2+1       size of p2blk in words
    see p1blk for definitions of pcode, pthen, parm1
    parm2 is a parameter which performs the same sort of
    function as parm1 (see description of p1blk).
    parm2 is a non-relocatable field and is not
    processed by the garbage collector. accordingly, it may
    not contain a pointer to a block in dynamic memory.
```

```
    program-defined datatype block
    a pdblk represents the data item formed by a call to a
    datatype function as defined by the system function data.
         +-----------------------------------+
         i                pdtyp              i
         +-----------------------------------+
         i                idval              i
         +-----------------------------------+
         i                pddfp              i
         +-----------------------------------+
         /                                   /
         /                pdfld              /
         /                                   /
         +-----------------------------------+
pdtyp   equ                   0       ptr to dummy routine b$pdt
pddfp   equ              idval+1      ptr to associated dfblk
pdfld   equ              pddfp+1      start of field value pointers
pdfof   equ          dffld-pdfld      difference in offset to field ptrs
pdsi$   equ                pdfld      size of standard fields in pdblk
pddfs   equ          dfsi$-pdsi$      difference in dfblk, pdblk sizes
    the pddfp pointer may be used to determine the datatype
    and the names of the fields if required. the dfblk also
    contains the length of the pdblk in bytes (field dfpdl).
    pddfp is non-reloc. because dfblk is in static
    pdfld values are stored in order from left to right.
    they contain values or pointers to trblk chains.
```

```
    program defined function block (pfblk)
    a pfblk is created for each call to the define function
    and a pointer to the pfblk placed in the proper vrblk.
         +-----------------------------------+
         i                fcode              i
         +-----------------------------------+
         i                fargs              i
         +-----------------------------------+
         i                pflen              i
         +-----------------------------------+
         i                pfvbl              i
         +-----------------------------------+
         i                pfnlo              i
         +-----------------------------------+
         i                pfcod              i
         +-----------------------------------+
         i                pfctr              i
         +-----------------------------------+
         i                pfrtr              i
         +-----------------------------------+
         /                                   /
         /                pfarg              /
         /                                   /
         +-----------------------------------+
pflen   equ             fargs+1      length of pfblk in bytes
pfvbl   equ             pflen+1      pointer to vrblk for function name
pfnlo   equ             pfvbl+1      number of locals
pfcod   equ             pfnlo+1      ptr to vrblk for entry label
pfctr   equ             pfcod+1      trblk ptr if call traced else 0
pfrtr   equ             pfctr+1      trblk ptr if return traced else 0
pfarg   equ             pfrtr+1      vrblk ptrs for arguments and locals
pfagb   equ             pfarg-1      offset behind pfarg for arg, local
pfsi$   equ               pfarg      number of standard fields in pfblk
    the fcode field points to the routine b$pfc.
    pfarg is stored in the following order.
         arguments (left to right)
         locals (left to right)
```

if **.cnra**

else

```
    real constant block (rcblk)
    an rcblk is created for every real referenced or
    created by a program.
         +-----------------------------------+
         i                rcget              i
         +-----------------------------------+
         *                rcval              *
         +-----------------------------------+
rcget   equ                   0       ptr to routine b$rcl to load real
rcval   equ             rcget+1       real value
rcsi$   equ         rcval+cfp$r       size of rcblk
    the length of the rcval field is cfp$r.
fi
```

```
    string constant block (scblk)
    an scblk is built for every string referenced or created
    by a program.
         +-----------------------------------+
         i                scget              i
         +-----------------------------------+
         i                sclen              i
         +-----------------------------------+
         /                                   /
         /                schar              /
         /                                   /
         +-----------------------------------+
scget   equ                   0       ptr to routine b$scl to load string
sclen   equ             scget+1       length of string in characters
schar   equ             sclen+1       characters of string
scsi$   equ               schar       size of standard fields in scblk
    the characters of the string are stored left justified.
    the final word is padded on the right with zeros.
    (i.e. the character whose internal code is zero).
    the value of sclen may not exceed mxlen. this ensures
    that character offsets (e.g. the pattern match cursor)
    can be correctly processed by the garbage collector.
    note that the offset to the characters of the string
    is given in bytes by cfp$f and that this value is
    automatically allowed for in plc, psc.
    note that for a spitbol scblk, the value of cfp$f
    is given by cfp$b*schar.
```

```
    simple expression block (seblk)
    an seblk is used to represent an expression of the form
    *(natural variable). all other expressions are exblks.
         +-----------------------------------+
         i                setyp              i
         +-----------------------------------+
         i                sevar              i
         +-----------------------------------+
setyp   equ                   0       ptr to routine b$sel to load expr
sevar   equ              setyp+1      ptr to vrblk for variable
sesi$   equ              sevar+1      length of seblk in words
```

```
standard variable block (svblk)
an svblk is assembled in the constant section for each
variable which satisfies one of the following conditions.
1)   it is the name of a system function
2)   it has an initial value
3)   it has a keyword association
4)   it has a standard i/o association
6)   it has a standard label association
if vrblks are constructed for any of these variables,
then the vrsvp field points to the svblk (see vrblk)
     +-----------------------------------+
     i                svbit              i
     +-----------------------------------+
     i                svlen              i
     +-----------------------------------+
     /                svchs              /
     +-----------------------------------+
     i                svknm              i
     +-----------------------------------+
     i                svfnc              i
     +-----------------------------------+
     i                svnar              i
     +-----------------------------------+
     i                svlbl              i
     +-----------------------------------+
     i                svval              i
     +-----------------------------------+
```

```
    standard variable block (continued)
svbit   equ                   0       bit string indicating attributes
svlen   equ                   1       (=sclen) length of name in chars
svchs   equ                   2       (=schar) characters of name
svsi$   equ                   2       number of standard fields in svblk
svpre   equ                   1       set if preevaluation permitted
svffc   equ          svpre+svpre      set on if fast call permitted
svckw   equ          svffc+svffc      set on if keyword value constant
svprd   equ          svckw+svckw      set on if predicate function
svnbt   equ                   4       number of bits to right of svknm
svknm   equ          svprd+svprd      set on if keyword association
svfnc   equ          svknm+svknm      set on if system function
svnar   equ          svfnc+svfnc      set on if system function
svlbl   equ          svnar+svnar      set on if system label
svval   equ          svlbl+svlbl      set on if predefined value
    note that the last five bits correspond in order
    to the fields which are present (see procedure gtnvr).
    the following definitions are used in the svblk table
svfnf   equ          svfnc+svnar      function with no fast call
svfnn   equ          svfnf+svffc      function with fast call, no preeval
svfnp   equ          svfnn+svpre      function allowing preevaluation
svfpr   equ          svfnn+svprd      predicate function
svfnk   equ          svfnn+svknm      no preeval func + keyword
svkwv   equ          svknm+svval      keyword + value
svkwc   equ          svckw+svknm      keyword with constant value
svkvc   equ          svkwv+svckw      constant keyword + value
svkvl   equ          svkvc+svlbl      constant keyword + value + label
svfpk   equ          svfnp+svkvc      preeval fcn + const keywd + val
    the svpre bit allows the compiler to preevaluate a call
    to the associated system function if all the arguments
    are themselves constants. functions in this category
    must have no side effects and must never cause failure.
    the call may generate an error condition.
    the svffc bit allows the compiler to generate the special
    fast call after adjusting the number of arguments. only
    the item and apply functions fall outside this category.
    the svckw bit is set if the associated keyword value is
    a constant, thus allowing preevaluation for a value call.
    the svprd bit is set on for all predicate functions to
    enable the special concatenation code optimization.
```

```
svblk (continued)
svknm                   keyword number
     svknm is present only for a standard keyword assoc.
     it contains a keyword number as defined by the
     keyword number table given later on.
svfnc                   system function pointer
     svfnc is present only for a system function assoc.
     it is a pointer to the actual code for the system
     function. the generated code for a fast call is a
     pointer to the svfnc field of the svblk for the
     function. the vrfnc field of the vrblk points to
     this same field, in which case, it serves as the
     fcode field for the function call.
svnar                   number of function arguments
     svnar is present only for a system function assoc.
     it is the number of arguments required for a call
     to the system function. the compiler uses this
     value to adjust the number of arguments in a fast
     call and in the case of a function called through
     the vrfnc field of the vrblk, the svnar field
     serves as the fargs field for o$fnc. a special
     case occurs if this value is set to 999. this is
     used to indicate that the function has a variable
     number of arguments and causes o$fnc to pass control
     without adjusting the argument count. the only
     predefined functions using this are apply and item.
svlbl                   system label pointer
     svlbl is present only for a standard label assoc.
     it is a pointer to a system label routine (l$xxx).
     the vrlbl field of the corresponding vrblk points to
     the svlbl field of the svblk.
svval                   system value pointer
     svval is present only for a standard value.
     it is a pointer to the pattern node (ndxxx) which
     is the standard initial value of the variable.
     this value is copied to the vrval field of the vrblk
```

```
    svblk (continued)
    keyword number table
    the following table gives symbolic names for keyword
    numbers. these values are stored in the svknm field of
    svblks and in the kvnum field of kvblks. see also

```
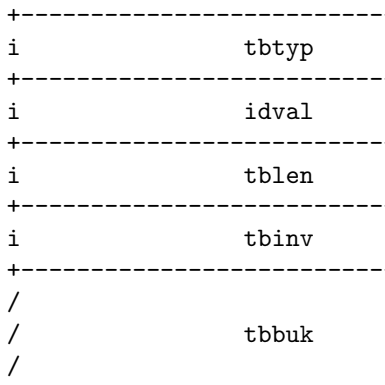
    format of a table block (tbblk)
    a table block is used to represent a table value.
    it is built by a call to the table or convert functions.
```



```
tbtyp   equ                 0       pointer to dummy routine b$tbt
tblen   equ              offs2      length of tbblk in bytes
tbinv   equ              offs3      default initial lookup value
tbbuk   equ            tbinv+1      start of hash bucket pointers
tbsi$   equ              tbbuk      size of standard fields in tbblk
tbnbk   equ                 11      default no. of buckets
    the table block is a hash table which points to chains
    of table element blocks representing the elements
    in the table which hash into the same bucket.
    tbbuk entries either point to the first teblk on the
    chain or they point to the tbblk itself to indicate the
    end of the chain.
```

```
    table element block (teblk)
    a table element is used to represent a single entry in
    a table (see description of tbblk format for hash table)
         +-----------------------------------+
         i                tetyp              i
         +-----------------------------------+
         i                tesub              i
         +-----------------------------------+
         i                teval              i
         +-----------------------------------+
         i                tenxt              i
         +-----------------------------------+
tetyp   equ                   0      pointer to dummy routine b$tet
tesub   equ             tetyp+1      subscript value
teval   equ             tesub+1      (=vrval) table element value
tenxt   equ             teval+1      link to next teblk
    see s$cnv where relation is assumed with tenxt and tbbuk
tesi$   equ             tenxt+1      size of teblk in words
    tenxt points to the next teblk on the hash chain from the
    tbbuk chain for this hash index. at the end of the chain,
    tenxt points back to the start of the tbblk.
    teval contains a data pointer or a trblk pointer.
    tesub contains a data pointer.
```

```
    trap block (trblk)
    a trap block is used to represent a trace or input or
    output association in response to a call to the trace
    input or output system functions. see below for details
         +-----------------------------------+
         i                tridn              i
         +-----------------------------------+
         i                trtyp              i
         +-----------------------------------+
         i  trval or trlbl or trnxt or trkvr  i
         +-----------------------------------+
         i       trtag or trter or trtrf      i
         +-----------------------------------+
         i            trfnc or trfpt          i
         +-----------------------------------+
```

tridn	**equ**	0	pointer to dummy routine b$trt
trtyp	**equ**	tridn+1	trap type code
trval	**equ**	trtyp+1	value of trapped variable (=vrval)
trnxt	**equ**	trval	ptr to next trblk on trblk chain
trlbl	**equ**	trval	ptr to actual label (traced label)
trkvr	**equ**	trval	vrblk pointer for keyword trace
trtag	**equ**	trval+1	trace tag
trter	**equ**	trtag	ptr to terminal vrblk or null
trtrf	**equ**	trtag	ptr to trblk holding fcblk ptr
trfnc	**equ**	trtag+1	trace function vrblk (zero if none)
trfpt	**equ**	trfnc	fcblk ptr for sysio
trsi$	**equ**	trfnc+1	number of words in trblk
trtin	**equ**	0	trace type for input association
trtac	**equ**	trtin+1	trace type for access trace
trtvl	**equ**	trtac+1	trace type for value trace
trtou	**equ**	trtvl+1	trace type for output association
trtfc	**equ**	trtou+1	trace type for fcblk identification

```
trap block (continued)
variable input association
     the value field of the variable points to a trblk
     instead of containing the data value. in the case
     of a natural variable, the vrget and vrsto fields
     contain =b$vra and =b$vrv to activate the check.
     trtyp is set to trtin
     trnxt points to next trblk or trval has variable val
     trter is a pointer to svblk if association is
     for input, terminal, else it is null.
     trtrf points to the trap block which in turn points
     to an fcblk used for i/o association.
     trfpt is the fcblk ptr returned by sysio.
variable access trace association
     the value field of the variable points to a trblk
     instead of containing the data value. in the case
     of a natural variable, the vrget and vrsto fields
     contain =b$vra and =b$vrv to activate the check.
     trtyp is set to trtac
     trnxt points to next trblk or trval has variable val
     trtag is the trace tag (0 if none)
     trfnc is the trace function vrblk ptr (0 if none)
variable value trace association
     the value field of the variable points to a trblk
     instead of containing the data value. in the case
     of a natural variable, the vrget and vrsto fields
     contain =b$vra and =b$vrv to activate the check.
     trtyp is set to trtvl
     trnxt points to next trblk or trval has variable val
     trtag is the trace tag (0 if none)
     trfnc is the trace function vrblk ptr (0 if none)
```

```
trap block (continued)
variable output association
     the value field of the variable points to a trblk
     instead of containing the data value. in the case
     of a natural variable, the vrget and vrsto fields
     contain =b$vra and =b$vrv to activate the check.
     trtyp is set to trtou
     trnxt points to next trblk or trval has variable val
     trter is a pointer to svblk if association is
     for output, terminal, else it is null.
     trtrf points to the trap block which in turn points
     to an fcblk used for i/o association.
     trfpt is the fcblk ptr returned by sysio.
function call trace
     the pfctr field of the corresponding pfblk is set
     to point to a trblk.
     trtyp is set to trtin
     trnxt is zero
     trtag is the trace tag (0 if none)
     trfnc is the trace function vrblk ptr (0 if none)
function return trace
     the pfrtr field of the corresponding pfblk is set
     to point to a trblk
     trtyp is set to trtin
     trnxt is zero
     trtag is the trace tag (0 if none)
     trfnc is the trace function vrblk ptr (0 if none)
label trace
     the vrlbl of the vrblk for the label is
     changed to point to a trblk and the vrtra field is
     set to b$vrt to activate the check.
     trtyp is set to trtin
     trlbl points to the actual label (cdblk) value
     trtag is the trace tag (0 if none)
     trfnc is the trace function vrblk ptr (0 if none)
```

```
trap block (continued)
keyword trace
     keywords which can be traced possess a unique
     location which is zero if there is no trace and
     points to a trblk if there is a trace. the locations
     are as follows.
     r$ert            errtype
     r$fnc            fnclevel
     r$stc            stcount
     the format of the trblk is as follows.
     trtyp is set to trtin
     trkvr is a pointer to the vrblk for the keyword
     trtag is the trace tag (0 if none)
     trfnc is the trace function vrblk ptr (0 if none)
input/output file arg1 trap block
     the value field of the variable points to a trblk
     instead of containing the data value. in the case of
     a natural variable, the vrget and vrsto fields
     contain =b$vra and =b$vrv. this trap block is used
     to hold a pointer to the fcblk which an
     implementation may request to hold information
     about a file.
     trtyp is set to trtfc
     trnext points to next trblk or trval is variable val
     trfnm is 0
     trfpt is the fcblk pointer.
note that when multiple traps are set on a variable
the order is in ascending value of trtyp field.
input association (if present)
access trace (if present)
value trace (if present)
output association (if present)
the actual value of the variable is stored in the trval
field of the last trblk on the chain.
this implementation does not permit trace or i/o
associations to any of the pseudo-variables.
```

```
    vector block (vcblk)
    a vcblk is used to represent an array value which has
    one dimension whose lower bound is one. all other arrays
    are represented by arblks. a vcblk is created by the
    system function array (s$arr) when passed an integer arg.
         +-----------------------------------+
         i                vctyp              i
         +-----------------------------------+
         i                idval              i
         +-----------------------------------+
         i                vclen              i
         +-----------------------------------+
         i                vcvls              i
         +-----------------------------------+
vctyp   equ                  0       pointer to dummy routine b$vct
vclen   equ               offs2      length of vcblk in bytes
vcvls   equ               offs3      start of vector values
vcsi$   equ               vcvls      size of standard fields in vcblk
vcvlb   equ            vcvls-1       offset one word behind vcvls
vctbd   equ       tbsi$-vcsi$        difference in sizes - see prtvl
    vcvls are either data pointers or trblk pointers
    the dimension can be deduced from vclen.
```

```
variable block (vrblk)
a variable block is built in the static memory area
for every variable referenced or created by a program.
the order of fields is assumed in the model vrblk stnvr.
note that since these blocks only occur in the static
region, it is permissible to point to any word in
the block and this is used to provide three distinct
access points from the generated code as follows.
1)   point to vrget (first word of vrblk) to load the
     value of the variable onto the main stack.
2)   point to vrsto (second word of vrblk) to store the
     top stack element as the value of the variable.
3)   point to vrtra (fourth word of vrblk) to jump to
     the label associated with the variable name.
     +-------------------------------------+
     i                vrget                i
     +-------------------------------------+
     i                vrsto                i
     +-------------------------------------+
     i                vrval                i
     +-------------------------------------+
     i                vrtra                i

     +-------------------------------------+
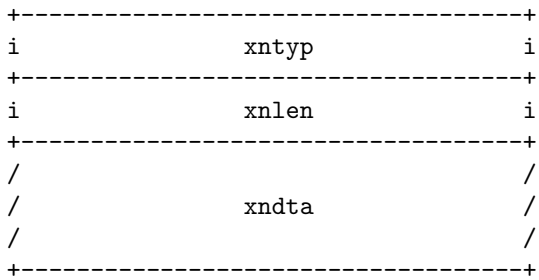
     i                vrlen                i
     +-------------------------------------+
     /                                     /
     /            vrchs = vrsvp            /
     /                                     /
     +-------------------------------------+
```

```
    variable block (continued)
vrget   equ                 0       pointer to routine to load value
vrsto   equ             vrget+1     pointer to routine to store value
vrval   equ             vrsto+1     variable value
vrvlo   equ         vrval-vrsto     offset to value from store field
vrtra   equ             vrval+1     pointer to routine to jump to label
vrlbl   equ             vrtra+1     pointer to code for label
vrlbo   equ         vrlbl-vrtra     offset to label from transfer field
vrfnc   equ             vrlbl+1     pointer to function block
vrnxt   equ             vrfnc+1     pointer to next vrblk on hash chain
vrlen   equ             vrnxt+1     length of name (or zero)
vrchs   equ             vrlen+1     characters of name (vrlen gt 0)
vrsvp   equ             vrlen+1     ptr to svblk (vrlen eq 0)
vrsi$   equ             vrchs+1     number of standard fields in vrblk
vrsof   equ         vrlen-sclen     offset to dummy scblk for name
vrsvo   equ         vrsvp-vrsof     pseudo-offset to vrsvp field
    vrget = b$vrl if not input associated or access traced
    vrget = b$vra if input associated or access traced
    vrsto = b$vrs if not output associated or value traced
    vrsto = b$vrv if output associated or value traced
    vrsto = b$vre if value is protected pattern value
    vrval points to the appropriate value unless the
    variable is i/o/trace associated in which case, vrval
    points to an appropriate trblk (trap block) chain.
    vrtra = b$vrg if the label is not traced
    vrtra = b$vrt if the label is traced
    vrlbl points to a cdblk if there is a label
    vrlbl points to the svblk svlbl field for a system label
    vrlbl points to stndl for an undefined label
    vrlbl points to a trblk if the label is traced
    vrfnc points to a ffblk for a field function
    vrfnc points to a dfblk for a datatype function
    vrfnc points to a pfblk for a program defined function
    vrfnc points to a efblk for an external loaded function
    vrfnc points to svfnc (svblk) for a system function
    vrfnc points to stndf if the function is undefined
    vrnxt points to the next vrblk on this chain unless
    this is the end of the chain in which case it is zero.
    vrlen is the name length for a non-system variable.
    vrlen is zero for a system variable.
    vrchs is the name (ljrz) if vrlen is non-zero.
    vrsvp is a ptr to the svblk if vrlen is zero.
```

```
    format of a non-relocatable external block (xnblk)
    an xnblk is a block representing an unknown (external)
    data value. the block contains no pointers to other
    relocatable blocks. an xnblk is used by external function
    processing or possibly for system i/o routines etc.
    the macro-system itself does not use xnblks.
    this type of block may be used as a file control block.
    see sysfc,sysin,sysou,s$inp,s$oup for details.
```



```
xntyp   equ                 0       pointer to dummy routine b$xnt
xnlen   equ           xntyp+1       length of xnblk in bytes
xndta   equ           xnlen+1       data words
xnsi$   equ             xndta       size of standard fields in xnblk
    note that the term non-relocatable refers to the contents
    and not the block itself. an xnblk can be moved around if
    it is built in the dynamic memory area.
```

```
    relocatable external block (xrblk)
    an xrblk is a block representing an unknown (external)
    data value. the data area in this block consists only
    of address values and any addresses pointing into the
    dynamic memory area must point to the start of other
    data blocks. see also description of xnblk.
    this type of block may be used as a file control block.
    see sysfc,sysin,sysou,s$inp,s$oup for details.

```
    definition of limits and adjustments that are built by
    relcr for use by the routines that relocate pointers
    after a save file is reloaded.  see reloc etc. for usage.
    a block of information is built that is used in
    relocating pointers.  there are rnsi$ instances
    of a rssi$ word structure.  each instance corresponds
    to one of the regions that a pointer might point into.
    each structure takes the form:
         +-----------------------------------+
         i    address past end of section    i
         +-----------------------------------+
         i  adjustment from old to new adrs  i
         +-----------------------------------+
         i    address of start of section    i
         +-----------------------------------+
    the instances are ordered thusly:
         +-----------------------------------+
         i           dynamic storage         i
         +-----------------------------------+
         i           static storage          i
         +-----------------------------------+
         i       working section globals     i
         +-----------------------------------+
         i          constant section         i
         +-----------------------------------+
         i            code section           i
         +-----------------------------------+
    symbolic names for these locations as offsets from
    the first entry are provided here.

    this section consists entirely of assembled constants.
    all label names are five letters. the order is
    approximately alphabetical, but in some cases (always
    documented), constants must be placed in some special
    order which must not be disturbed.
    it must also be remembered that there is a requirement
    for no forward references which also disturbs the
    alphabetical order in some cases.

    last location in constant section
c$yyy   dac                 0       last location in constant section
```

```
the working storage section contains areas which are
changed during execution of the program. the value
assembled is the initial value before execution starts.
all these areas are fixed length areas. variable length
data is stored in the static or dynamic regions of the
allocated data areas.
the values in this area are described either as work
areas or as global values. a work area is used in an
ephemeral manner and the value is not saved from one
entry into a routine to another. a global value is a
less temporary location whose value is saved from one
call to another.
w$aaa marks the start of the working section whilst
w$yyy marks its end.  g$aaa marks the division between
temporary and global values.
global values are further subdivided to facilitate
processing by the garbage collector. r$aaa through
r$yyy are global values that may point into dynamic
storage and hence must be relocated after each garbage
collection.  they also serve as root pointers to all
allocated data that must be preserved.  pointers between
a$aaa and r$aaa may point into code, static storage,
or mark the limits of dynamic memory.  these pointers
must be adjusted when the working section is saved to a
file and subsequently reloaded at a different address.
a general part of the approach in this program is not
to overlap work areas between procedures even though a
small amount of space could be saved. such overlap is
considered a source of program errors and decreases the
information left behind after a system crash of any kind.
the names of these locations are labels with five letter
(a-y,$) names. as far as possible the order is kept
alphabetical by these names but in some cases there
are slight departures caused by other order requirements.
unless otherwise documented, the order of work areas
does not affect the execution of the spitbol program.

    adjustable global values
    all the pointers in this section can point to the
    dynamic or the static region.
    when a save file is reloaded, these pointers must
    be adjusted if static or dynamic memory is now
    at a different address.  see routine reloc for
    additional information.
    some values cannot be move here because of adjacency
    constraints.  they are handled specially by reloc et al.
    these values are kvrtn,
    values gtswk, kvalp, and prbuf are reinitialized by
    procedure insta, and do not need to appear here.
    values flprt, flptr, gtcef, and stbas point into the
    stack and are explicitly adjusted by osint's restart
    procedure.

this section includes all routines which can be accessed
directly from the generated code except system functions.
all routines in this section start with a label of the
form o$xxx where xxx is three letters. the generated code
contains a pointer to the appropriate entry label.
since the general form of the generated code consists of
pointers to blocks whose first word is the address of the
actual entry point label (o$xxx).
these routines are in alphabetical order by their
entry label names (i.e. by the xxx of the o$xxx name)
these routines receive control as follows
(cp)                  pointer to next code word
(xs)                  current stack pointer
```

```
    the first word of every block in dynamic storage and the
    vrget, vrsto and vrtra fields of a vrblk contain a
    pointer to an entry point in the program. all such entry
    points are in the following section except those for
    pattern blocks which are in the pattern matching segment
    later on (labels of the form p$xxx), and dope vectors
    (d$xxx) which are in the dope vector section following
    the pattern routines (dope vectors are used for cmblks).
    the entry points in this section have labels of the
    form b$xxy where xx is the two character block type for
    the corresponding block and y is any letter.
    in some cases, the pointers serve no other purpose than
    to identify the block type. in this case the routine
    is never executed and thus no code is assembled.
    for each of these entry points corresponding to a block
    an entry point identification is assembled (bl$xx).
    the exact entry conditions depend on the manner in
    which the routine is accessed and are documented with
    the individual routines as required.
    the order of these routines is alphabetical with the
    following exceptions.
    the routines for seblk and exblk entries occur first so
    that expressions can be quickly identified from the fact
    that their routines lie before the symbol b$e$$.
    these are immediately followed by the routine for a trblk
    so that the test against the symbol b$t$$ checks for
    trapped values or expression values (see procedure evalp)
    the pattern routines lie after this section so that
    patterns are identified with routines starting at or
    after the initial instruction in these routines (p$aaa).
    the symbol b$aaa defines the first location for block
    routines and the symbol p$yyy (at the end of the pattern
    match routines section) defines the last such entry point
b$aaa   ent                 bl$$i       entry point of first block routine
```

```
    exblk
    the routine for an exblk loads the expression onto
    the stack as a value.
    (xr)                    pointer to exblk
b$exl   ent                 bl$ex       entry point (exblk)

```

```
    vcblk
    the routine for a vcblk is never executed
b$vct   ent                 bl$vc       entry point (vcblk)
```

```
    vrblk
    the vrblk routines are executed from the generated code.
    there are six entries for vrblk covering various cases
b$vr$   ent               bl$$i      mark start of vrblk entry points
    entry for vrget (trapped case). this routine is called
    from the generated code to load the value of a variable.
    this entry point is used if an access trace or input
    association is currently active.
    (xr)                  pointer to vrget field of vrblk
b$vra   ent               bl$$i      entry point
        mov               xr,xl      copy name base (vrget = 0)
        mov           *vrval,wa      set name offset
        jsr               acess      access value
        ppm               exfal      fail if access fails
        mov            xr,-(xs)      stack result
        lcw                  xr      get next code word
        bri               (xr)       execute it
```

```
    vrblk (continued)
    entry for vrsto (error case. this routine is called from
    the executed code for an attempt to modify the value
    of a protected (pattern valued) natural variable.
b$vre   ent                         entry point
        erb     042,attempt to c    value of protected variable
```

```
    vrblk (continued)
    entry for vrtra (untrapped case). this routine is called
    from the executed code to transfer to a label.
    (xr)                  pointer to vrtra field of vrblk
b$vrg   ent                             entry point
        mov         vrlbo(xr),xr        load code pointer
        mov              (xr),xl        load entry address
        bri                   xl        jump to routine for next code word
```

```
    vrblk (continued)
    entry for vrget (untrapped case). this routine is called
    from the generated code to load the value of a variable.
    (xr)                  points to vrget field of vrblk
b$vrl   ent                             entry point
        mov     vrval(xr),-(xs)         load value onto stack (vrget = 0)
        lcw                 xr          get next code word
        bri                (xr)         execute next code word
```

```
    vrblk (continued)
    entry for vrsto (untrapped case). this routine is called
    from the generated code to store the value of a variable.
    (xr)                    pointer to vrsto field of vrblk
b$vrs   ent                             entry point
        mov       (xs),vrvlo(xr)        store value, leave on stack
        lcw                   xr        get next code word
        bri                 (xr)        execute next code word
```

```
    vrblk (continued)
    vrtra (trapped case). this routine is called from the
    generated code to transfer to a label when a label
    trace is currently active.
b$vrt   ent                             entry point
        sub             *vrtra,xr       point back to start of vrblk
        mov                 xr,xl       copy vrblk pointer
        mov             *vrval,wa       set name offset
        mov         vrlbl(xl),xr        load pointer to trblk
        bze          kvtra,bvrt2        jump if trace is off
        dcv                 kvtra       else decrement trace count
        bze      trfnc(xr),bvrt1        jump if print trace case
        jsr                 trxeq       else execute full trace
        brn                 bvrt2       merge to jump to label
    here for print trace -- print colon ( label name )
bvrt1   jsr                 prtsn       print statement number
        mov                 xl,xr       copy vrblk pointer
        mov             =ch$cl,wa       colon

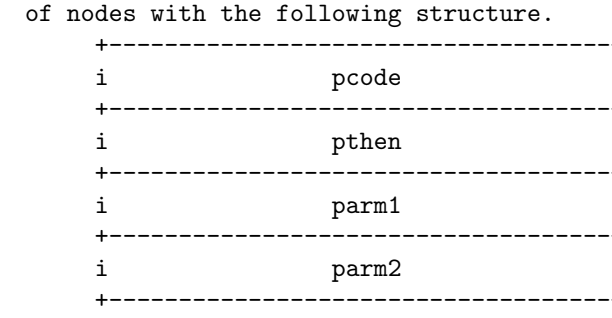
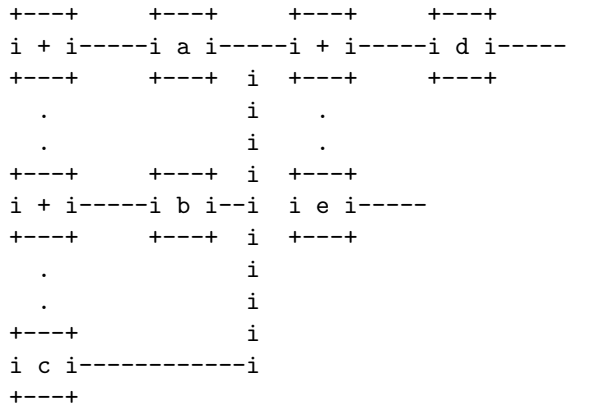
    mark entry address past last block action routine
b$yyy   ent               bl$$i       last block routine entry point
```

```
    the following section consists of the pattern matching
    routines. all pattern nodes contain a pointer (pcode)
    to one of the routines in this section (p$xxx).
    note that this section follows the b$xxx routines to
    enable a fast test for the pattern datatype.
p$aaa   ent               bl$$i       entry to mark first pattern
    the entry conditions to the match routine are as follows
    (see o$pmn, o$pmv, o$pms and procedure match).
    stack contents.
                          name base (o$pmn only)
                          name offset (o$pmn only)
                          type (0-o$pmn, 1-o$pmv, 2-o$pms)
    pmhbs ---------------- initial cursor (zero)
                          initial node pointer
    xs ------------------ =ndabo (anchored), =nduna (unanch)
    register values.
         (xs)             set as shown in stack diagram
         (xr)             pointer to initial pattern node
         (wb)             initial cursor (zero)
    global pattern values
         r$pms            pointer to subject string scblk
         pmssl            length of subject string in chars
         pmdfl            dot flag, initially zero
         pmhbs            set as shown in stack diagram
    control is passed by branching through the pcode
    field of the initial pattern node (bri (xr)).
```

description of algorithm
a pattern structure is represented as a linked graph
of nodes with the following structure.



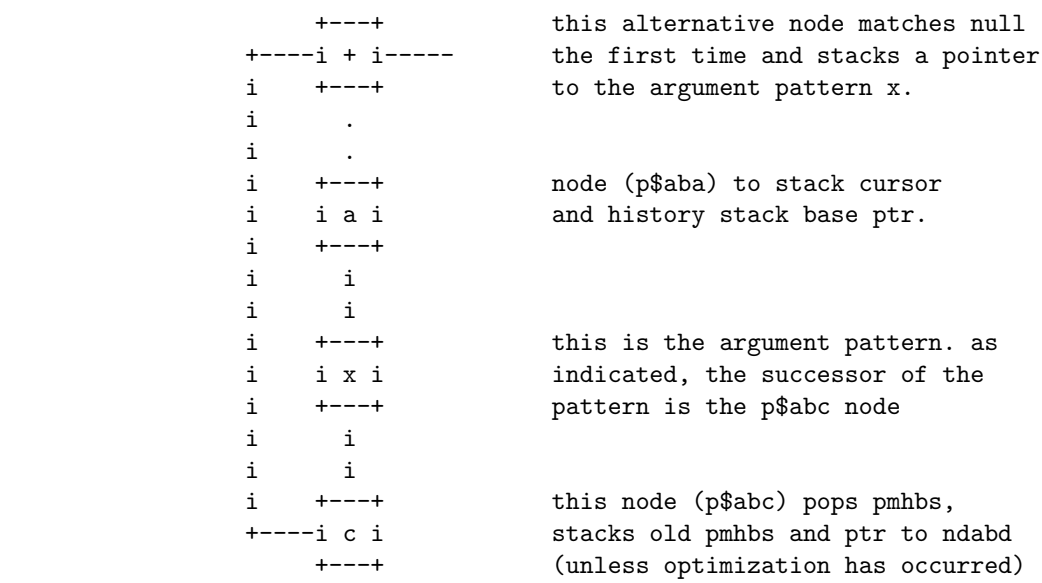
pcode is a pointer to the routine which will perform
the match of this particular node type.
pthen is a pointer to the successor node. i.e. the node
to be matched if the attempt to match this node succeeds.
if this is the last node of the pattern pthen points
to the dummy node ndnth which initiates pattern exit.
parm1, parm2 are parameters whose use varies with the
particular node. they are only present if required.
alternatives are handled with the special alternative
node whose parameter points to the node to be matched
if there is a failure on the successor path.
the following example illustrates the manner in which
the structure is built up. the pattern is
(a / b / c) (d / e)   where / is alternation
in the diagram, the node marked + represents an
alternative node and the dotted line from a + node
represents the parameter pointer to the alternative.



```
during the match, the registers are used as follows.
(xr)                    points to the current node
(xl)                    scratch
(xs)                    main stack pointer
(wb)                    cursor (number of chars matched)
(wa,wc)                 scratch
to keep track of alternatives, the main stack is used as
a history stack and contains two word entries.
word 1                  saved cursor value
word 2                  node to match on failure
when a failure occurs, the most recent entry on this
stack is popped off to restore the cursor and point
to the node to be matched as an alternative. the entry
at the bottom of the stack points to the following
special nodes depending on the scan mode.
anchored mode           the bottom entry points to the
                        special node ndabo which causes an
                        abort. the cursor value stored
                        with this entry is always zero.
unanchored mode         the bottom entry points to the
                        special node nduna which moves the
                        anchor point and restarts the match
                        the cursor saved with this entry
                        is the number of characters which
                        lie before the initial anchor point
                        (i.e. the number of anchor moves).
                        this entry is three words long and
                        also contains the initial pattern.
entries are made on this history stack by alternative
nodes and by some special compound patterns as described
later on. the following global locations are used during
pattern matching.
r$pms                   pointer to subject string
pmssl                   length of subject string
pmdfl                   flag set non-zero for dot patterns
pmhbs                   base ptr for current history stack
the following exit points are available to match routines
succp                   success in matching current node
failp                   failure in matching current node
```

```
compound patterns
some patterns have implicit alternatives and their
representation in the pattern structure consists of a
linked set of nodes as indicated by these diagrams.
as before, the + represents an alternative node and
the dotted line from a + node is the parameter pointer
to the alternative pattern.
arb
---
     +---+            this node (p$arb) matches null
     i b i-----       and stacks cursor, successor ptr,
     +---+            cursor (copy) and a ptr to ndarc.
bal
---
     +---+            the p$bal node scans a balanced
     i b i-----       string and then stacks a pointer
     +---+            to itself on the history stack.
```

compound pattern structures (continued)
arbno



structure and execution of this pattern resemble those of recursive pattern matching and immediate assignment. the alternative node at the head of the structure matches null initially but on subsequent failure ensures attempt to match the argument. before the argument is matched p$aba stacks the cursor, pmhbs and a ptr to p$abb. if the argument cant be matched , p$abb removes this special stack entry and fails.

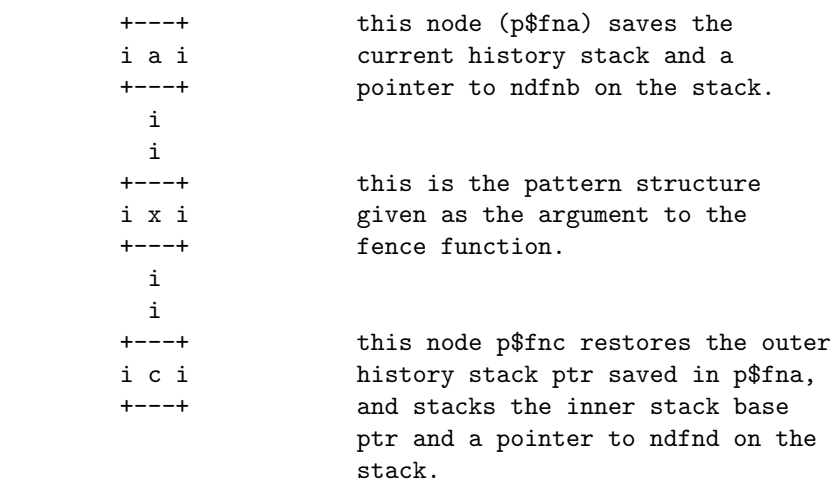
if argument is matched , p$abc restores the outer pmhbs value (saved by p$aba) . then if the argument has left alternatives on stack it stacks the inner value of pmhbs and a ptr to ndabd. if argument left nothing on the stack it optimises by removing items stacked by p$aba. finally a check is made that argument matched more than the null string (check is intended to prevent useless looping). if so the successor is again the alternative node at the head of the structure , ensuring a possible extra attempt to match the arg if necessary. if not , the successor to alternative is taken so as to terminate the loop. p$abd restores inner pmhbs ptr and fails , thus trying to match alternatives left by the arbno argument.

```
compound pattern structures (continued)
breakx
------
     +---+            this node is a break node for
+----i b i            the argument to breakx, identical
i    +---+            to an ordinary break node.
i      i
i      i
i    +---+            this alternative node stacks a
i    i + i-----       pointer to the breakx node to
i    +---+            allow for subsequent failure
i      .
i      .
i    +---+            this is the breakx node itself. it
+----i x i            matches one character and then
     +---+            proceeds back to the break node.
fence
-----
     +---+            the fence node matches null and
     i f i-----       stacks a pointer to node ndabo to
     +---+            abort on a subsequent rematch
succeed
-------
     +---+            the node for succeed matches null
     i s i-----       and stacks a pointer to itself
     +---+            to repeat the match on a failure.
```

```
     +---+            this node (p$paa) saves the current
     i a i            cursor and a pointer to the
     +---+            special node ndpab on the stack.
       i
       i
     +---+            this is the structure for the
     i x i            pattern left argument of the
     +---+            pattern assignment call.
       i
       i
     +---+            this node (p$pac) saves the cursor,
     i c i-----       a ptr to itself, the cursor (copy)
     +---+            and a ptr to ndpad on the stack.
```

the function of the match routine for ndpab (p$pab)
is simply to unstack itself and fail back onto the stack.
the match routine for p$pac also sets the global pattern
flag pmdfl non-zero to indicate that pattern assignments
may have occured in the pattern match
if pmdfl is set at the end of the match (see p$nth), the
history stack is scanned for matching ndpab-ndpad pairs
and the corresponding pattern assignments are executed.
the function of the match routine for ndpad (p$pad)
is simply to remove its entry from the stack and fail.
this includes removing the special node pointer stored
in addition to the standard two entries on the stack.

compount pattern structures (continued)
fence (function)



ndfnb (f$fnb) simply is the failure exit for pattern
argument failure, and it pops itself and fails onto the
stack.
the match routine p$fnc allows for an optimization when
the fence pattern leaves no alternatives. in this case,
the ndfnb entry is popped, and the match continues.
ndfnd (p$fnd) is entered when the pattern fails after
going through a non-optimized p$fnc, and it pops the
stack back past the innter stack base created by p$fna

expression patterns (recursive pattern matches)

initial entry for a pattern node is to the routine p$exa.
if the evaluated result of the expression is itself a
pattern, then the following steps are taken to arrange
for proper recursive processing.

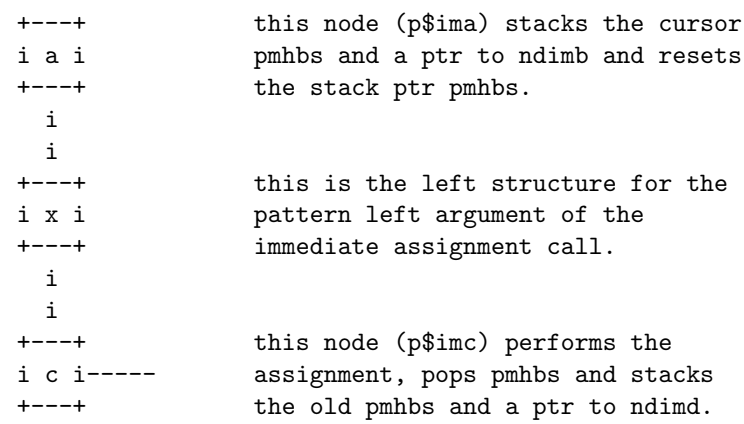
1) a pointer to the current node (the p$exa node) is
   stored on the history stack with a dummy cursor.
2) a special history stack entry is made in which the
   node pointer points to ndexb, and the cursor value
   is the saved value of pmhbs on entry to this node.
   the match routine for ndexb (p$exb) restores pmhbs
   from this cursor entry, pops off the p$exa node
   pointer and fails.
3) the resulting history stack pointer is saved in
   pmhbs to establish a new level of history stack.

after matching a pattern, the end of match routine gets
control (p$nth). this routine proceeds as follows.

1) load the current value of pmhbs and recognize the
   outer level case by the fact that the associated
   cursor in this case is the pattern match type code
   which is less than 3. terminate the match in this
   case and continue execution of the program.
2) otherwise make a special history stack entry in
   which the node pointer points to the special node
   ndexc and the cursor is the current value of pmhbs.
   the match routine for ndexc (p$exc) resets pmhbs to
   this (inner) value and and then fails.
3) using the history stack entry made on starting the
   expression (accessible with the current value of
   pmhbs), restore the p$exa node pointer and the old
   pmhbs setting. take the successor and continue.

an optimization is possible if the expression pattern
makes no entries on the history stack. in this case,
instead of building the p$exc node in step 2, it is more
efficient to simply pop off the p$exb entry and its
associated node pointer. the effect is the same.

compound patterns (continued)
binary dollar (immediate assignment)



the structure and execution of this pattern are similar
to those of the recursive expression pattern matching.
the match routine for ndimb (p$imb) restores the outer
level value of pmhbs, unstacks the saved cursor and fails
the match routine p$imc uses the current value of pmhbs
to locate the p$imb entry. this entry is used to make
the assignment and restore the outer level value of
pmhbs. finally, the inner level value of pmhbs and a
pointer to the special node ndimd are stacked.
the match routine for ndimd (p$imd) restores the inner
level value of pmhbs and fails back into the stack.
an optimization occurs if the inner pattern makes no
entries on the history stack. in this case, p$imc pops
the p$imb entry instead of making a p$imd entry.

```

the following section contains coding for functions
which are predefined and available at the snobol level.
these routines receive control directly from the code or
indirectly through the o$fnc, o$fns or cfunc routines.
in both cases the conditions on entry are as follows
the arguments are on the stack. the number of arguments
has been adjusted to correspond to the svblk svnar field.
in certain functions the direct call is not permitted
and in these instances we also have.
(wa)                    actual number of arguments in call
control returns by placing the function result value on
on the stack and continuing execution with the next
word from the generated code.
the names of the entry points of these functions are of
the form s$xxx where xxx is the three letter code for
the system variable name. the functions are in order
alphabetically by their entry names.

    replace
    the actual replace operation uses an scblk whose cfp$a
    chars contain the translated versions of all the chars.
    the table pointer is remembered from call to call and
    the table is only built when the arguments change.
    we also perform an optimization gleaned from spitbol 370.
    if the second argument is &alphabet, there is no need to
    to build a replace table.  the third argument can be
    used directly as the replace table.
s$rpl   ent                             entry point
        jsr                 gtstg       load third argument as string
        err     168,replace thir        argument is not a string
        mov                 xr,xl       save third arg ptr
        jsr                 gtstg       get second argument
        err     169,replace seco        argument is not a string
    check to see if this is the same table as last time
        bne       xr,r$ra2,srpl1        jump if 2nd argument different
        beq       xl,r$ra3,srpl4        jump if args same as last time
    here we build a new replace table (note wa = 2nd arg len)
srpl1   mov         sclen(xl),wb        load 3rd argument length
        bne           wa,wb,srpl6       jump if arguments not same length
        beq       xr,kvalp,srpl5        jump if 2nd arg is alphabet string
        bze             wb,srpl6        jump if null 2nd argument
        mov             xl,r$ra3        save third arg for next time in
        mov             xr,r$ra2        save second arg for next time in
        mov             kvalp,xl        point to alphabet string
        mov         sclen(xl),wa        load alphabet scblk length
        mov             r$rpt,xr        point to current table (if any)

```

```
the following section contains utility routines used for
various purposes throughout the system. these differ
from the procedures in the utility procedures section in
they are not in procedure form and they do not return
to their callers. they are accessed with a branch type
instruction after setting the registers to appropriate
parameter values.
the register values required for each routine are
documented at the start of each routine. registers not
mentioned may contain any values except that xr,xl
can only contain proper collectable pointers.
some of these routines will tolerate garbage pointers
in xl,xr on entry. this is always documented and in
each case, the routine clears these garbage values before
exiting after completing its task.
the routines have names consisting of five letters
and are assembled in alphabetical order.
```

```
    arref -- array reference
    (xl)                  may be non-collectable
    (xr)                  number of subscripts
    (wb)                  set zero/nonzero for value/name
                          the value in wb must be collectable
    stack                 subscripts and array operand
    brn  arref            jump to call function
    arref continues by executing the next code word with
    the result name or value placed on top of the stack.
    to deal with the problem of accessing subscripts in the
    order of stacking, xl is used as a subscript pointer
    working below the stack pointer.
arref   rtn                exits

```
the following section contains procedures which are
used for various purposes throughout the system.
each procedure is preceded by a description of the
calling sequence. usually the arguments are in registers
but arguments can also occur on the stack and as
parameters assembled after the jsr instruction.
the following considerations apply to these descriptions.
1)   the stack pointer (xs) is not changed unless the
     change is explicitly documented in the call.
2)   registers whose entry values are not mentioned
     may contain any value except that xl,xr may only
     contain proper (collectable) pointer values.
     this condition on means that the called routine
     may if it chooses preserve xl,xr by stacking.
3)   registers not mentioned on exit contain the same
     values as they did on entry except that values in
     xr,xl may have been relocated by the collector.
4)   registers which are destroyed on exit may contain
     any value except that values in xl,xr are proper
     (collectable) pointers.
5)   the code pointer register points to the current
     code location on entry and is unchanged on exit.
in the above description, a collectable pointer is one
which either points outside the dynamic region or
points to the start of a block in the dynamic region.
in those cases where the calling sequence contains
parameters which are used as alternate return points,
these parameters may be replaced by error codes
assembled with the err instruction. this will result
in the posting of the error if the return is taken.
the procedures all have names consisting of five letters
and are in alphabetical order by their names.
```

```
    acess - access variable value with trace/input checks
    acess loads the value of a variable. trace and input
    associations are tested for and executed as required.
    acess also handles the special cases of pseudo-variables.
    (xl)                variable name base
    (wa)                variable name offset
    jsr  acess          call to access value
    ppm  loc            transfer loc if access failure
    (xr)                variable value
    (wa,wb,wc)          destroyed
    (xl,ra)             destroyed
    failure can occur if an input association causes an end
    of file condition or if the evaluation of an expression
    associated with an expression variable fails.
acess   prc                 r,1     entry point (recursive)

```
    asign -- perform assignment
    asign performs the assignment of a value to a variable
    with appropriate checks for output associations and
    value trace associations which are executed as required.
    asign also handles the special cases of assignment to
    pattern and expression variables.
    (wb)                value to be assigned
    (xl)                base pointer for variable
    (wa)                offset for variable
    jsr  asign          call to assign value to variable
    ppm  loc            transfer loc for failure
    (xr,xl,wa,wb,wc)    destroyed
    (ra)                destroyed
    failure occurs if the evaluation of an expression
    associated with an expression variable fails.
asign  prc                r,1       entry point (recursive)
    merge back here to assign result to expression variable.
asg01  add                wa,xl     point to variable value

    cdgnm -- generate code by name
    cdgnm is called during the compilation process to
    generate code by name for an expression. see cdblk
    description for details of code generated. the input
    to cdgnm is an expression tree as generated by expan.
    cdgnm is a recursive procedure which proceeds by making
    recursive calls to generate code for operands.
    (wb)                integer in range 0 le n le dnamb
    (xr)                ptr to tree generated by expan
    (wc)                constant flag (see below)
    jsr  cdgnm          call to generate code by name
    (xr,wa)             destroyed
    (wc)                set non-zero if non-constant
    wc is set to a non-zero (collectable) value if the
    expression for which code is generated cannot be
    evaluated at compile time, otherwise wc is unchanged.
    the code is generated in the current ccblk (see cdwrd).
cdgnm   prc                 r,0      entry point, recursive

```
    cdgvl -- generate code by value
    cdgvl is called during the compilation process to
    generate code by value for an expression. see cdblk
    description for details of the code generated. the input
    to cdgvl is an expression tree as generated by expan.
    cdgvl is a recursive procedure which proceeds by making
    recursive calls to generate code for operands.
    (wb)                integer in range 0 le n le dnamb
    (xr)                ptr to tree generated by expan
    (wc)                constant flag (see below)
    jsr  cdgvl          call to generate code by value
    (xr,wa)             destroyed
    (wc)                set non-zero if non-constant
    wc is set to a non-zero (collectable) value if the
    expression for which code is generated cannot be
    evaluated at compile time, otherwise wc is unchanged.
    if wc is non-zero on entry, then preevaluation is not
    allowed regardless of the nature of the operand.
    the code is generated in the current ccblk (see cdwrd).
cdgvl   prc                 r,0       entry point, recursive
        mov             (xr),wa       load type word

    cmgen -- generate code for cmblk ptr
    cmgen is a subsidiary procedure used to generate value
    code for a cmblk ptr from the main code generators.
    (xl)                cmblk pointer
    (wb)                offset to pointer in cmblk
    jsr  cmgen          call to generate code
    (xr,wa)             destroyed
    (wb)                bumped by one word
cmgen   prc               r,0       entry point, recursive
        mov             xl,xr       copy cmblk pointer
        add             wb,xr       point to cmblk pointer
        mov           (xr),xr       load cmblk pointer
        jsr             cdgvl       generate code by value
        ica               wb        bump offset
        exi                         return to caller
        enp                         end procedure cmgen
```

```
cmpil (compile source code)
cmpil is used to convert snobol4 source code to internal
form (see cdblk format). it is used both for the initial
compile and at run time by the code and convert functions
this procedure has control for the entire duration of
initial compilation. an error in any procedure called
during compilation will lead first to the error section
and ultimately back here for resumed compilation. the
re-entry points after an error are specially labelled -
cmpce                  resume after control card error
cmple                  resume after label error
cmpse                  resume after statement error
jsr  cmpil             call to compile code
(xr)                   ptr to cdblk for entry statement
(xl,wa,wb,wc,ra)       destroyed
the following global variables are referenced
cmpln                  line number of first line of
                       statement to be compiled
cmpsn                  number of next statement
                       to be compiled.
cswxx                  control card switch values are
                       changed when relevant control
                       cards are met.
cwcof                  offset to next word in code block
                       being built (see cdwrd).
lstsn                  number of statement most recently
                       compiled (initially set to zero).
r$cim                  current (initial) compiler image
                       (zero for initial compile call)
r$cni                  used to point to following image.
                       (see readr procedure).
scngo                  goto switch for scane procedure
scnil                  length of current image excluding
                       characters removed by -input.
scnpt                  current scan offset, see scane.
scnrs                  rescan switch for scane procedure.
scnse                  offset (in r$cim) of most recently
                       scanned element. set zero if not
                       currently scanning items
```

```
cmpil (continued)
stage               stgic  initial compile in progress
                    stgxc  code/convert compile
                    stgev  building exblk for eval
                    stgxt  execute time (outside compile)
                    stgce  initial compile after end line
                    stgxe  execute compile after end line
cmpil also uses a fixed number of locations on the
main stack as follows. (the definitions of the actual
offsets are in the definitions section).
cmstm(xs)             pointer to expan tree for body of
                      statement (see expan procedure).
cmsgo(xs)             pointer to tree representation of
                      success goto (see procedure scngo)
                      zero if no success goto is given
cmfgo(xs)             like cmsgo for failure goto.
cmcgo(xs)             set non-zero only if there is a
                      conditional goto. used for -fail,
                      -nofail code generation.
cmpcd(xs)             pointer to cdblk for previous
                      statement. zero for 1st statement.
cmffp(xs)             set non-zero if cdfal in previous
                      cdblk needs filling with forward
                      pointer, else set to zero.
cmffc(xs)             same as cmffp for current cdblk
cmsop(xs)             offset to word in previous cdblk
                      to be filled in with forward ptr
                      to next cdblk for success goto.
                      zero if no fill in is required.
cmsoc(xs)             same as cmsop for current cdblk.
cmlbl(xs)             pointer to vrblk for label of
                      current statement. zero if no label
cmtra(xs)             pointer to cdblk for entry stmnt.

    dumpr -- print dump of storage
    (xr)                  dump argument (see below)
    jsr  dumpr            call to print dump
    (xr,xl)               destroyed
    (wa,wb,wc,ra)         destroyed
    the dump argument has the following significance
    dmarg = 0             no dump printed
    dmarg = 1             partial dump (nat vars, keywords)
    dmarg = 2             full dump (arrays, tables, etc.)
    dmarg = 3             full dump + null variables
    dmarg ge 4            core dump
    since dumpr scrambles store, it is not permissible to
    collect in mid-dump. hence a collect is done initially
    and then if store runs out an error message is produced.
dumpr   prc                   e,0       entry point

        jsr                 prtnl       terminate print line
        jsr                 prtnl       and print a blank line
    first all natural variable blocks (vrblk) whose values
    are non-null are linked in lexical order using dmvch as
    the chain head and chaining through the vrget fields.
    note that this scrambles store if the process is
    interrupted before completion e.g. by exceeding time  or
    print limits. since the subsequent core dumps and
    failures if execution is resumed are very confusing, the
    execution time error routine checks for this event and
    attempts an unscramble. similar precautions should be
    observed if translate time dumping is implemented.

```
    evalp -- evaluate expression during pattern match
    evalp is used to evaluate an expression (by value) during
    a pattern match. the effect is like evalx, but pattern
    variables are stacked and restored if necessary.
    evalp also differs from evalx in that if the result is
    an expression it is reevaluated. this occurs repeatedly.
    to support optimization of pos and rpos, evalp uses wc
    to signal the caller for the case of a simple vrblk
    that is not an expression and is not trapped.  because
    this case cannot have any side effects, optimization is
    possible.
    (xr)                node pointer
    (wb)                pattern match cursor
    jsr  evalp          call to evaluate expression

```
expan -- analyze expression
the expression analyzer (expan) procedure is used to scan
an expression and convert it into a tree representation.
see the description of cmblk in the structures section
for detailed format of tree blocks.
the analyzer uses a simple precedence scheme in which
operands and operators are placed on a single stack
and condensations are made when low precedence operators
are stacked after a higher precedence operator. a global
variable (in wb) keeps track of the level as follows.
0    scanning outer level of statement or expression
1    scanning outer level of normal goto
2    scanning outer level of direct goto
3    scanning inside array brackets
4    scanning inside grouping parentheses
5    scanning inside function parentheses
this variable is saved on the stack on encountering a
grouping and restored at the end of the grouping.
another global variable (in wc) counts the number of
items at one grouping level and is incremented for each
comma encountered. it is stacked with the level indicator
the scan is controlled by a three state finite machine.
a global variable stored in wa is the current state.
wa=0                  nothing scanned at this level
wa=1                  operand expected
wa=2                  operator expected
(wb)                  call type (see below)
jsr  expan            call to analyze expression
(xr)                  pointer to resulting tree
(xl,wa,wb,wc,ra)      destroyed
the entry value of wb indicates the call type as follows.
0    scanning either the main body of a statement or the
     text of an expression (from eval call). valid
     terminators are colon, semicolon. the rescan flag is
     set to return the terminator on the next scane call.
1    scanning a normal goto. the only valid
     terminator is a right paren.
2    scanning a direct goto. the only valid
     terminator is a right bracket.
```

    gbcol -- perform garbage collection
    gbcol performs a garbage collection on the dynamic region
    all blocks which are no longer in use are eliminated
    by moving blocks which are in use down and resetting
    dnamp, the pointer to the next available location.
    (wb)                move offset (see below)
    jsr  gbcol          call to collect garbage
if .csed
    (xr)                sediment size after collection
else
    (xr)                destroyed
fi
    the following conditions must be met at the time when
    gbcol is called.
    1)   all pointers to blocks in the dynamic area must be
         accessible to the garbage collector. this means
         that they must occur in one of the following.
         a)             main stack, with current top
                        element being indicated by xs
         b)             in relocatable fields of vrblks.
         c)             in register xl at the time of call
         e)             in the special region of working
                        storage where names begin with r$.
    2)   all pointers must point to the start of blocks with
         the sole exception of the contents of the code
         pointer register which points into the r$cod block.
    3)   no location which appears to contain a pointer
         into the dynamic region may occur unless it is in
         fact a pointer to the start of the block. however
         pointers outside this area may occur and will
         not be changed by the garbage collector.
         it is especially important to make sure that xl
         does not contain a garbage value from some process
         carried out before the call to the collector.
    gbcol has the capability of moving the final compacted
    result up in memory (with addresses adjusted accordingly)
    this is used to add space to the static region. the
    entry value of wb is the number of bytes to move up.
    the caller must guarantee that there is enough room.
    furthermore the value in wb if it is non-zero, must be at
    least 256 so that the mwb instruction conditions are met.
```

gbcol (continued)
the algorithm, which is a modification of the lisp-2
garbage collector devised by r.dewar and k.belcher
takes three passes as follows.

1) all pointers in memory are scanned and blocks in use
   determined from this scan. note that this procedure
   is recursive and uses the main stack for linkage.
   the marking process is thus similar to that used in
   a standard lisp collector. however the method of
   actually marking the blocks is different.
   the first field of a block normally contains a
   code entry point pointer. such an entry pointer
   can be distinguished from the address of any pointer
   to be processed by the collector. during garbage
   collection, this word is used to build a back chain
   of pointers through fields which point to the block.
   the end of the chain is marked by the occurence
   of the word which used to be in the first word of
   the block. this backchain serves both as a mark
   indicating that the block is in use and as a list of
   references for the relocation phase.
2) storage is scanned sequentially to discover which
   blocks are currently in use as indicated by the
   presence of a backchain. two pointers are maintained
   one scans through looking at each block. the other
   is incremented only for blocks found to be in use.
   in this way, the eventual location of each block can
   be determined without actually moving any blocks.
   as each block which is in use is processed, the back
   chain is used to reset all pointers which point to
   this block to contain its new address, i.e. the
   address it will occupy after the blocks are moved.
   the first word of the block, taken from the end of
   the chain is restored at this point.
   during pass 2, the collector builds blocks which
   describe the regions of storage which are to be
   moved in the third pass. there is one descriptor for
   each contiguous set of good blocks. the descriptor
   is built just behind the block to be moved and
   contains a pointer to the next block and the number
   of words to be moved.
3) in the third and final pass, the move descriptor
   blocks built in pass two are used to actually move
   the blocks down to the bottom of the dynamic region.
   the collection is then complete and the next
   available location pointer is reset.

```
    gbcol (continued)
if .csed
    the garbage collector also recognizes the concept of
    sediment.  sediment is defined as long-lived objects
    which percipitate to the bottom of dynamic storage.
    moving these objects during repeated collections is
    inefficient.  it also contributes to thrashing on
    systems with virtual memory.  in a typical worst-case
    situation, there may be several megabytes of live objects
    in the sediment, and only a few dead objects in need of
    collection.  without recognising sediment, the standard
    collector would move those megabytes of objects downward
    to squeeze out the dead objects.  this type of move
    would result in excessive thrasing for very little memory
    gain.
    scanning of blocks in the sediment cannot be avoided
    entirely, because these blocks may contain pointers to
    live objects above the sediment.  however, sediment
    blocks need not be linked to a back chain as described
    in pass one above.  since these blocks will not be moved,
    pointers to them do not need to be adjusted.  eliminating
    unnecessary back chain links increases locality of
    reference, improving virtual memory performance.
    because back chains are used to mark blocks whose con-
    tents have been processed, a different marking system
if .cepp
    is needed for blocks in the sediment.  since block type
    words point to odd-parity entry addresses, merely incre-
    menting the type word serves to mark the block as pro-
    cessed.  during pass three, the type words are decre-
    mented to restore them to their original value.
else
    is needed for blocks in the sediment.  all block type
    words normally lie in the range b$aaa to p$yyy.  blocks
    can be marked by adding an offset (created in gbcmk) to
    move type words out of this range.  during pass three the
    offset is subtracted to restore them to their original
    value.
fi
```

```
gbcol (continued)
the variable dnams contains the number of bytes of memory
currently in the sediment.  setting dnams to zero will
eliminate the sediment and force it to be included in a
full garbage collection.  gbcol returns a suggested new
value for dnams (usually dnamp-dnamb) in xr which the
caller can store in dnams if it wishes to maintain the
sediment.  that is, data remaining after a garbage
collection is considered to be sediment.  if one accepts
the common lore that most objects are either very short-
or very long-lived, then this naive setting of dnams
probably includes some short-lived objects toward the end
of the sediment.
knowing when to reset dnams to zero to collect the sedi-
ment is not precisely known.  we force it to zero prior
to producing a dump, when gbcol is invoked by collect()
(so that the sediment is invisible to the user), when
sysmm is unable to obtain additional memory, and when
gbcol is called to relocate the dynamic area up in memory
(to make room for enlarging the static area).  if there
are no other reset situations, this leads to the inexo-
rable growth of the sediment, possible forcing a modest
program to begin to use virtual memory that it otherwise
would not.
as we scan sediment blocks in pass three, we maintain
aggregate counts of the amount of dead and live storage,
which is used to decide when to reset dnams.  when the
ratio of free storage found in the sediment to total
sediment size exceeds a threshold, the sediment is marked
for collection on the next gbcol call.

    now we are ready to start pass two. registers are used
    as follows in pass two.
    (xr)                  scans through all blocks
    (wc)                  pointer to eventual location
    the move description blocks built in this pass have
    the following format.
    word 1                pointer to next move block,
                          zero if end of chain of blocks
    word 2                length of blocks to be moved in
                          bytes. set to the address of the
                          first byte while actually scanning
                          the blocks.
    the first entry on this chain is a special entry
    consisting of the two words gbcnm and gbcns. after
    building the chain of move descriptors, gbcnm points to
    the first real move block, and gbcns is the length of
    blocks in use at the start of storage which need not
    be moved since they are in the correct position.

        dvr               (xr)      and complete scaling
        str              gtsrs      store value
    we are now scaled, so round by adding 0.5 * 10**(-cfp$s)
gts17   ldr              gtsrs      get value again
        adr              gtsrn      add rounding factor
        str              gtsrs      store result
    the rounding operation may have pushed us up past
    1.0 again, so check one more time.
        sbr              reav1      subtract 1.0 to compare
        rlt              gts18      skip if ok
        adi              intv1      else increment exponent
        ldr              gtsrs      reload value
        dvr              reavt      divide by 10.0 to rescale
        brn              gts19      jump to merge
    here if rounding did not muck up scaling
gts18   ldr              gtsrs      reload rounded value
```

```
    gtstg (continued)
    now we have completed the scaling as follows
    (ia)                  signed exponent
    (ra)                  scaled real (absolute value)
    if the exponent is negative or greater than cfp$s, then
    we convert the number in the form.
    (neg sign) 0 . (cpf$s digits) e (exp sign) (exp digits)
    if the exponent is positive and less than or equal to
    cfp$s, the number is converted in the form.
    (neg sign) (exponent digits) . (cfp$s-exponent digits)
    in both cases, the formats obtained from the above
    rules are modified by deleting trailing zeros after the
    decimal point. there are no leading zeros in the exponent
    and the exponent sign is always present.
gts19   mov           =cfp$s,xl      set num dec digits = cfp$s
        mov       =ch$mn,gtses       set exponent sign negative
        ilt               gts21      all set if exponent is negative
        mfi                  wa      else fetch exponent

    insbf -- insert string in buffer
    this routine will replace a section of a buffer with the
    contents of a given string.  if the length of the
    section to be replaced is different than the length of
    the given string, and the replacement is not an append,
    then the upper section of the buffer is shifted up or
    down to create the proper space for the insert.
    (xr)                  pointer to bcblk
    (xl)                  object which is string convertable
    (wa)                  offset of start of insert in buffer
    (wb)                  length of section to replace
    jsr  insbf            call to insert characters in buffer
    ppm  loc              thread if (xl) not convertable
    ppm  loc              thread if insert not possible
    the second alternate exit is taken if the insert would
    overflow the buffer, or if the insert is out past the
    defined end of the buffer as given.

    pconc -- concatenate two patterns
    (xl)                    ptr to right pattern
    (xr)                    ptr to left pattern
    jsr  pconc              call to concatenate patterns
    (xr)                    ptr to concatenated pattern
    (xl,wa,wb,wc)           destroyed
    to concatenate two patterns, all successors in the left
    pattern which point to the nothen node must be changed to
    point to the right pattern. however, this modification
    must be performed on a copy of the left argument rather
    than the left argument itself, since the left argument
    may be pointed to by some other variable value.
    accordingly, it is necessary to copy the left argument.
    this is not a trivial process since we must avoid copying
    nodes more than once and the pattern is a graph structure
    the following algorithm is employed.
    the stack is used to store a list of nodes which
    have already been copied. the format of the entries on
    this list consists of a two word block. the first word
    is the old address and the second word is the address
    of the copy. this list is searched by the pcopy
    routine to avoid making duplicate copies. a trick is
    used to accomplish the concatenation at the same time.
    a special entry is made to start with on the stack. this
    entry records that the nothen node has been copied
    already and the address of its copy is the right pattern.
    this automatically performs the correct replacements.
pconc   prc                   e,0       entry point
        zer                  -(xs)      make room for one entry at bottom

```

```
    prtnm -- print variable name
    prtnm is used to print a character representation of the
    name of a variable (not a value of datatype name)
    names of pseudo-variables may not be passed to prtnm.
    (xl)                    name base
    (wa)                    name offset
    jsr  prtnm              call to print name
    (wb,wc,ra)              destroyed
prtnm   prc                   r,0       entry point (recursive, see prtvl)
        mov             wa,-(xs)        save wa (offset is collectable)
        mov             xr,-(xs)        save entry xr
        mov             xl,-(xs)        save name base
        bhi       xl,state,prn02        jump if not natural variable
    here for natural variable name, recognized by the fact
    that the name base points into the static area.
        mov                 xl,xr       point to vrblk
        jsr                 prtvn       print name of variable
    common exit point
prn01   mov             (xs)+,xl        restore name base
        mov             (xs)+,xr        restore entry value of xr
        mov             (xs)+,wa        restore wa
        exi                             return to prtnm caller
    here for case of non-natural variable
prn02   mov                 wa,wb       copy name offset
        bne     (xl),=b$pdt,prn0        jump if array or table
    for program defined datatype, prt fld name, left paren
        mov        pddfp(xl),xr         load pointer to dfblk
        add                 wa,xr       add name offset
        mov        pdfof(xr),xr         load vrblk pointer for field
        jsr                 prtvn       print field name
        mov           =ch$pp,wa         load left paren
        jsr                 prtch       print character
```

```
    prtnm (continued)
    now we print an identifying name for the object if one
    can be found. the following code searches for a natural
    variable which contains this object as value. if such a
    variable is found, its name is printed, else the value
    of the object (as printed by prtvl) is used instead.
    first we point to the parent tbblk if this is the case of
    a table element. to do this, chase down the trnxt chain.
prn03   bne     (xl),=b$tet,prn0      jump if we got there (or not te)
        mov        tenxt(xl),xl       else move out on chain
        brn                prn03      and loop back
    now we are ready for the search. to speed things up in
    the case of calls from dump where the same name base
    will occur repeatedly while dumping an array or table,
    we remember the last vrblk pointer found in prnmv. so
    first check to see if we have this one again.
prn04   mov             prnmv,xr      point to vrblk we found last time
        mov             hshtb,wa      point to hash table in case not
        brn                prn07      jump into search for special check
    loop through hash slots
prn05   mov                wa,xr      copy slot pointer
        ica                   wa      bump slot pointer
        sub            *vrnxt,xr      introduce standard vrblk offset
    loop through vrblks on one hash chain
prn06   mov        vrnxt(xr),xr       point to next vrblk on hash chain
    merge here first time to check block we found last time
prn07   mov                xr,wc      copy vrblk pointer
        bze             wc,prn09      jump if chain end (or prnmv zero)
```

```
    prtnm (continued)
    loop to find value (chase down possible trblk chain)
prn08   mov       vrval(xr),xr      load value
        beq    (xr),=b$trt,prn0     loop if that was a trblk
    now we have the value, is this the block we want
        beq         xr,xl,prn10     jump if this matches the name base
        mov               wc,xr     else point back to that vrblk
        brn               prn06     and loop back
    here to move to next hash slot
prn09   blt       wa,hshte,prn05    loop back if more to go
        mov               xl,xr     else not found, copy value pointer
        jsr               prtvl     print value
        brn               prn11     and merge ahead
    here when we find a matching entry
prn10   mov               wc,xr     copy vrblk pointer
        mov            xr,prnmv     save for next time in
        jsr               prtvn     print variable name
    merge here if no entry found
prn11   mov             (xl),wc     load first word of name base
        bne     wc,=b$pdt,prn13     jump if not program defined
    for program defined datatype, add right paren and exit

```
scane -- scan an element
scane is called at compile time (by expan ,cmpil,cncrd)
to scan one element from the input image.
(scncc)               non-zero if called from cncrd
jsr  scane            call to scan element
(xr)                  result pointer (see below)
(xl)                  syntax type code (t$xxx)
the following global locations are used.
r$cim                 pointer to string block (scblk)
                      for current input image.
r$cni                 pointer to next input image string
                      pointer (zero if none).
r$scp                 save pointer (exit xr) from last
                      call in case rescan is set.
scnbl                 this location is set non-zero on
                      exit if scane scanned past blanks
                      before locating the current element
                      the end of a line counts as blanks.
scncc                 cncrd sets this non-zero to scan
                      control card names and clears it
                      on return
scnil                 length of current input image
scngo                 if set non-zero on entry, f and s
                      are returned as separate syntax
                      types (not letters) (goto pro-
                      cessing). scngo is reset on exit.
scnpt                 offset to current loc in r$cim
scnrs                 if set non-zero on entry, scane
                      returns the same result as on the
                      last call (rescan). scnrs is reset
                      on exit from any call to scane.
scntp                 save syntax type from last
                      call (in case rescan is set).

    scngf -- scan goto field
    scngf is called from cmpil to scan and analyze a goto
    field including the surrounding brackets or parentheses.
    for a normal goto, the result returned is either a vrblk
    pointer for a simple label operand, or a pointer to an
    expression tree with a special outer unary operator
    (o$goc). for a direct goto, the result returned is a
    pointer to an expression tree with the special outer
    unary operator o$god.
    jsr  scngf            call to scan goto field
    (xr)                  result (see above)

sorta -- sort array
routine to sort an array or table on same basis as in
sitbol. a table is converted to an array, leaving two
dimensional arrays and vectors as cases to be considered.
whole rows of arrays are permuted according to the
ordering of the keys they contain, and the stride
referred to, is the the length of a row. it is one
for a vector.
the sort used is heapsort, fundamentals of data structure
horowitz and sahni, pitman 1977, page 347.
it is an order n*log(n) algorithm. in order
to make it stable, comparands may not compare equal. this
is achieved by sorting a copy array (referred to as the
sort array) containing at its high address end, byte
offsets to the rows to be sorted held in the original
array (referred to as the key array). sortc, the
comparison routine, accesses the keys through these
offsets and in the case of equality, resolves it by
comparing the offsets themselves. the sort permutes the
offsets which are then used in a final operation to copy
the actual items into the new array in sorted order.
references to zeroth item are to notional item
preceding first actual item.
reverse sorting for rsort is done by having the less than
test for keys effectively be replaced by a
greater than test.

```

```
xscan -- execution function argument scan
xscan scans out one token in a prototype argument in
array,clear,data,define,load function calls. xscan
calls must be preceded by a call to the initialization
procedure xscni. the following variables are used.
r$xsc                 pointer to scblk for function arg
xsofs                 offset (num chars scanned so far)
(wa)                  non-zero to skip and trim blanks
(wc)                  delimiter one (ch$xx)
(xl)                  delimiter two (ch$xx)
jsr  xscan            call to scan next item
(xr)                  pointer to scblk for token scanned
(wa)                  completion code (see below)
(wc,xl)               destroyed
the scan starts from the current position and continues
until one of the following three conditions occurs.
1)   delimiter one is encountered  (wa set to 1)
2)   delimiter two encountered  (wa set to 2)
3)   end of string encountered  (wa set to 0)
the result is a string containing all characters scanned
up to but not including any delimiter character.
the pointer is left pointing past the delimiter.
if only one delimiter is to be detected, delimiter one
and delimiter two should be set to the same value.
in the case where the end of string is encountered, the
string includes all the characters to the end of the
string. no further calls can be made to xscan until
xscni is called to initialize a new argument scan
```

```

    error during initial compile
    the error message is printed as part of the compiler
    output. this printout includes the offending line (if not
    printed already) and an error flag under the appropriate
    column as indicated by scnse unless scnse is set to zero.
    after printing the message, the generated code is
    modified to an error call and control is returned to
    the cmpil procedure after resetting the stack pointer.
    if the error occurs after the end line, control returns
    in a slightly different manner to ensure proper cleanup.

    error at execute time.
    the action taken on an error is as follows.
    if errlimit keyword is zero, an abort is signalled,
    see coding for system label abort at l$abo.
    otherwise, errlimit is decremented and an errtype trace
    generated if required. control returns either via a jump
    to continue (to take the failure exit) or a specified
    setexit trap is executed and control passes to the trap.
    if 3 or more fatal errors occur an abort is signalled
    regardless of errlimit and setexit - looping is all too
    probable otherwise. fatal errors include stack overflow
    and exceeding stlimit.
